The Proven Con

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

siderate Rescue

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.[1]

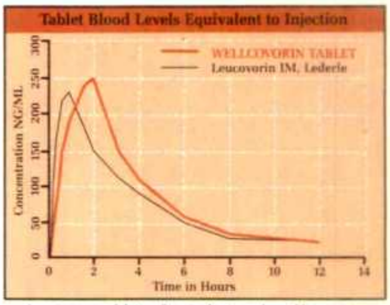
[1] Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 100) and 25 mg (scored, bottles of 25).



Average serum folates after single 15 mg dose of leucovorin administered either IM or orally. Adapted from Blum, et al.

Blum MR, Guaspari A, Liao SHT, et al: Bioavailability and pharmacokinetics of oral and parenteral leucovorin. 33rd National Meeting Pharm. Sci. San Diego, California. 1982. 12(2):175.

86WCV1

WELLCOVORIN® TABLETS

(leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

When workers aren't there, business doesn't work.

Each year cancer strikes 120,000 people in our work force, and causes our economy to lose more than $10 billion in earnings. Earnings that American workers might still be generating if they had known the simple facts on how to protect themselves from cancer.

Protect your employees, your company, and yourself. . .call your local unit of the American Cancer Society and ask for their free pamphlet, "Helping Your Employees to Protect Themselves Against Cancer." Start your company on a policy of good health today!

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

first recombinant Interferon into the clinic

With more than a decade of dedicated research, Roche leads the way in identifying, purifying and engineering the first recombinant alfa Interferon

In 1969, scientists at the Roche Institute of Molecular Biology began the intensive work that culminated in the production of alfa Interferon in *E. coli* cells by means of gene-splicing and cloning technology. An advanced technique of affinity chromatography using monoclonal antibodies assures a virtually pure product.

Multicenter study included 6 leading cancer centers...large patient data base

In 1981, ROFERON-A became the first recombinant Interferon used in clinical trials at six leading cancer centers throughout the United States. The remarkable clinical response achieved in these trials established ROFERON-A as breakthrough biotherapy for hairy cell leukemia.

Study utilized fixed-dosage SC or IM injectable solution to permit self-injection by patient or administration by family member in the home

Home administration reduces the demands on busy medical staff and spares the patient time, travel "wear and tear" and expense of making frequent office or clinic visits.

Fixed-dosage SC or IM injectable solution allows administration without calculation in home, office or institution...saves time, cost-effective

Elimination of weight or body surface area calculation results in more efficient administration with less waste of time and medication. Available as ready-to-use injectable solution with no mixing or reconstitution necessary.

Common side effects usually self-limiting and manageable

Initial side effects, such as fever, chills, myalgia, headache and fatigue, are self-limiting and generally manageable. Myelosuppression, which can occur early in the treatment course, warrants close clinical and laboratory observation and is usually alleviated by dose reduction or temporary discontinuation of drug.

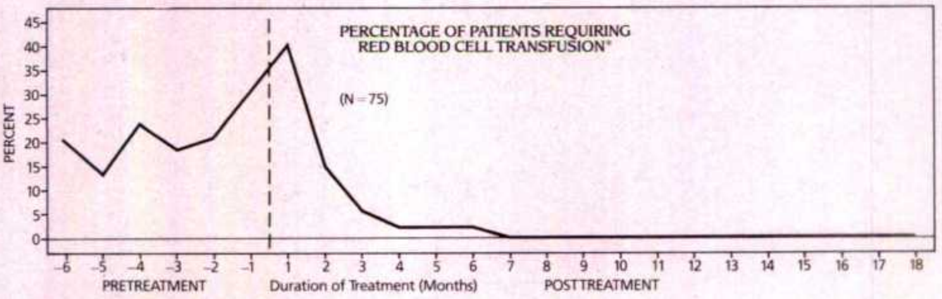
[*] Multicenter Study, Data on file, Hoffmann-La Roche Inc., Nutley, NJ.

[†] Of the 75, 57 had prior splenectomy and 18 had not; many were pancytopenic and transfusion-dependent; 96 patients were enrolled in study and all were evaluated for safety; 21 patients were not evaluable; 16 were not on drug long enough for efficacy evaluation at time of data analysis, 2 were removed for administrative reasons, 3 for preexisting intercurrent illness.

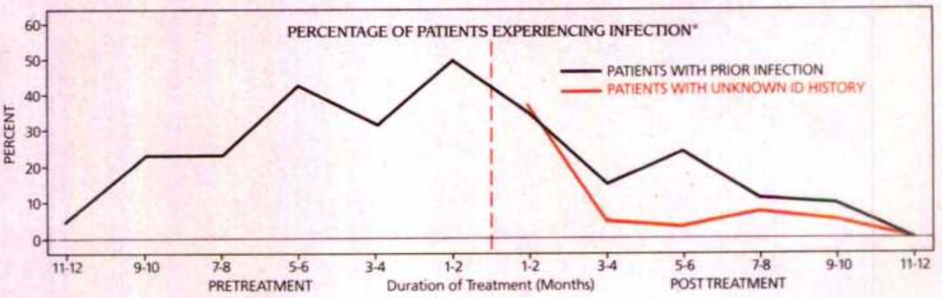
A new modality...
ROCHE Leading the way in biotherapeutics

a better quality of life

From transfusion dependency to independent ambulatory treatment



From frequent life-threatening opportunistic infections to virtually none



*Multicenter Study, Data on file, Hoffmann-La Roche Inc., Nutley, NJ.

From frequent hospital visits to self-injection at home

After an initial period of hospital or clinic visits for drug administration, self-injection at home or administration by a family member makes it possible for many patients to lead a more normal life.

From the serious, difficult-to-manage side effects of chemotherapy to the more manageable side effects of biotherapy

The common side effects of ROFERON-A are rarely as debilitating as some of the serious side effects associated with standard chemotherapy and radiotherapy. (See side effects listed on following pages and in complete product information on last pages of this advertisement.)

From weight loss to weight stabilization

In a multicenter study, 86% of patients on ROFERON-A experienced no change in, or gained up to 10% of, their total body weight.

Guidelines to treatment

Patient selection

ROFERON-A (Interferon alfa-2a, recombinant/Roche) is indicated for symptomatic adult patients. It should be used with caution in patients with preexisting cardiac disease, renal and hepatic disease, myelosuppression, seizure disorders and/or compromised central nervous system function.

Information for patients

Patients should be cautioned not to change brands of Interferon without medical consultation, as a change in dosage may result. They should also be informed regarding the potential benefits and risks attendant to the use of ROFERON-A. If home use is judged desirable, instructions on appropriate use and self-injection should be given.

Patients should be well hydrated, especially during the initial stages of treatment.

Dosage and administration

Induction:	**3 million IU SC or IM once daily for 6 months.**
Maintenance:	**3 million IU SC or IM 3 times a week.**
Dosage Reduction:	**If severe reactions occur, reduce dosage by 50% or withhold individual doses.**

How supplied

Ready-to-use Injectable Solution: Unit-dose vials containing 3 million IU (3 million IU/mL); multidose vials containing 18 million IU (3 million IU/0.5 mL).
No mixing or reconstitution necessary.
Must be refrigerated at temperatures of 36° to 46°F (2° to 8°C). At no time should ROFERON-A (Interferon alfa-2a, recombinant/Roche) Injectable Solution remain outside of refrigeration for more than 24 hours. Be certain all users, including physicians, nurses and patients are aware of this important precaution. Do *not* freeze or shake.

Directions for use

The subcutaneous or intramuscular routes of administration should be used. Subcutaneous administration is particularly suggested for, but not limited to, patients who are significantly thrombocytopenic or at risk for bleeding.

Side effects: generally mild and manageable

Pretreatment

Routine history and physical examination. Determine baseline values: CBC, peripheral and bone marrow hairy cells, liver and renal function.

Those patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer should have electrocardiograms taken prior to and during the course of treatment.

Flu-like symptoms

The most common initial reactions, fever, chills, myalgia, headache and fatigue, are usually self-limiting and can be ameliorated by acetaminophen.

Myelosuppressive effect

The myelosuppressive effect warrants careful monitoring for depression of blood cell

ROCHE Leading the way in biotherapeutics

counts during initial therapy and is usually alleviated by dose reduction or temporary discontinuation of drug.

Other common but generally mild side effects

These include anorexia, nausea, vomiting, diarrhea, dizziness, rash, change in taste, dry mouth or throat, dry skin or pruritus and weight loss. Persistent mild fatigue, a problem for many patients, is usually found to be less troublesome when ROFERON-A is administered *p.m.* or *h.s.*

Rarely reported but more serious side effects

These include, but are not limited to, central nervous system effects such as decreased mental status, depression, visual disturbances, sleep disturbances and nervousness, as well as such adverse cardiac events as hypertension, chest pain, arrhythmias and palpitations.

Patient monitoring

Monitor blood parameters, liver and renal function periodically (*e.g.*, monthly) to determine if patient is responding to and tolerating drug. Response is not generally observed for one to three months. Patients usually should be treated for approximately six months before determining whether to continue therapy.

Patients with hairy cell leukemia have been treated for up to 20 consecutive months. The optimal duration of treatment for this disease has not been determined.

Laboratory findings

No patient had to be removed from multicenter study due to clinical laboratory abnormality.

Laboratory abnormalities, observed frequently but generally not of clinical significance, include:

SGOT elevation

Common but not dose-limiting

Neutralizing antibodies

Found in four out of 51 (7.8%) patients in multicenter study evaluable for the development of antibodies; no clinical sequelae or adverse effect on response, duration of response or survival has been noted thus far.

NOTE: Antibodies to human leukocyte interferon may occur spontaneously in certain clinical conditions (cancer, systemic lupus erythematosus, herpes zoster) in patients who have never received exogenous interferon.

Contraindications

ROFERON-A is contraindicated in patients with known hypersensitivity to alfa interferon, mouse immunoglobulin or any component of the product.

Use in fertile women

Fertile women should use effective contraception while receiving ROFERON-A.

NEW SC/IM

ROFERON®-A

BRAND OF Interferon alfa-2a, recombinant/Roche

Before prescribing, please see complete product information on last pages of this advertisement.

NEW SC/IM

ROFERON®-A

BRAND OF
Interferon alfa-2a, recombinant/Roche

DESCRIPTION: Roferon®-A (Interferon alfa-2a, recombinant/Roche) is a sterile protein product for use by injection. Roferon-A is manufactured by recombinant DNA technology that employs a genetically engineered *E. coli* bacterium containing DNA that codes for the human protein. Interferon alfa-2a, recombinant/Roche is a highly purified protein containing 165 amino acids, and it has an approximate molecular weight of 19,000 daltons. The purification procedure includes affinity chromatography using a murine monoclonal antibody. Roferon-A is supplied as an injectable solution. The solution is colorless and contains Interferon alfa-2a, recombinant/Roche, phenol as a preservative, sodium chloride for isotonicity and human serum albumin as a stabilizer. Fermentation is carried out in a defined nutrient medium containing the antibiotic tetracycline hydrochloride, 5 mg/liter. However, the presence of the antibiotic is not detectable in the final product.

Each vial of Roferon-A contains 3 million or 18 million international units (IU) of Interferon alfa-2a, recombinant/Roche. The specific activity of Interferon alfa-2a, recombinant/Roche, is 2×10^8 IU/mg protein. The route of administration is subcutaneous or intramuscular.

CLINICAL PHARMACOLOGY: The mechanism by which Interferon alfa-2a, recombinant/Roche, or any other interferon, exerts antitumor activity is not clearly understood. However, it is believed that direct antiproliferative action against tumor cells and modulation of the host immune response play important roles in the antitumor activity.

The biological activities of Interferon alfa-2a, recombinant/Roche are species-restricted, *i.e.*, they are expressed in a very limited number of species other than humans. As a consequence, preclinical evaluation of Interferon alfa-2a, recombinant/Roche has involved *in vitro* experiments with human cells and some *in vivo* experiments.[1] Using human cells in culture, Interferon alfa-2a, recombinant/Roche has been shown to have antiproliferative and immunomodulatory activities that are very similar to those of the mixture of interferon alfa subtypes produced by human leukocytes. *In vivo*, Interferon alfa-2a, recombinant/Roche has been shown to inhibit the growth of several human tumors growing in immunocompromised (nude) mice.

Because of its species-restricted activity, it has not been possible to demonstrate antitumor activity in immunologically intact syngeneic tumor model systems, where effects on the host immune system would be observable. However, such antitumor activity has been repeatedly demonstrated with, for example, mouse interferon-alfa in transplantable mouse tumor systems. The clinical significance of these findings is unknown.

The metabolism of Interferon alfa-2a, recombinant/Roche is consistent with that of alfa interferons in general. Alfa interferons are totally filtered through the glomeruli and undergo rapid proteolytic degradation during tubular reabsorption, rendering a negligible reappearance of intact alfa interferon in the systemic circulation. Small amounts of radiolabeled Interferon alfa-2a, recombinant/Roche appear in the urine of isolated rat kidneys, suggesting near complete reabsorption of Interferon alfa-2a, recombinant/Roche catabolites. Liver metabolism and subsequent biliary excretion are considered minor pathways of elimination for alfa interferons.

The serum concentrations of Interferon alfa-2a, recombinant/Roche reflected a large intersubject variation in both healthy volunteers and patients with disseminated cancer.

In healthy people, Interferon alfa-2a, recombinant/Roche exhibited an elimination half-life of 3.7 to 8.5 hours (mean 5.1 hours), volume of distribution at steady-state of 0.223 to 0.748 L/kg (mean 0.400 L/kg) and a total body clearance of 2.14 to 3.62 mL/min/kg (mean 2.79 mL/min/kg) after a 36 million IU (2.2×10^8 pg) intravenous infusion. After intramuscular and subcutaneous administrations of 36 million IU, peak serum concentrations ranged from 1500 to 2580 pg/mL (mean 2020 pg/mL) at a mean time to peak of 3.8 hours and from 1250 to 2320 pg/mL (mean 1730 pg/mL) at a mean time to peak of 7.3 hours, respectively. The apparent fraction of the dose absorbed after intramuscular injection was greater than 80%.

The pharmacokinetics of Interferon alfa-2a, recombinant/Roche after single intramuscular doses to patients with disseminated cancer were similar to those found in healthy volunteers. Dose proportional increases in serum concentrations were observed after single doses up to 198 million IU. There were no changes in the distribution or elimination of Interferon alfa-2a, recombinant/Roche during twice daily (0.5 to 36 million IU), once daily (1 to 54 million IU), or three times weekly (1 to 136 million IU) dosing regimens up to 28 days of dosing. Multiple intramuscular doses of Interferon alfa-2a, recombinant/Roche resulted in an accumulation of 2 to 4 times the single dose serum concentrations. Pharmacokinetic information in patients with hairy cell leukemia is presently unknown.

The acute parenteral toxicity of Interferon alfa-2a, recombinant/Roche has been studied in mice, rats, rabbits and ferrets at doses up to 30 million IU/kg intravenously, and 500 million IU/kg intramuscularly. No treatment-related mortality was noted in any species given Interferon alfa-2a, recombinant/Roche by any of the routes of administration.

Effects on Hairy Cell Leukemia: During the first one to two months of treatment of patients with hairy cell leukemia, significant depression of hematopoiesis was likely to occur. Subsequently, there was improvement in circulating blood cell counts.

Of the 75 patients who were evaluable for efficacy following at least 16 weeks of therapy, 46 (61%) achieved complete or partial response. Twenty-one patients (28%) had a minor remission, eight (11%) remained stable, and none had worsening of disease. All patients who achieved either a complete or partial response had complete or partial normalization of all peripheral blood elements including hemoglobin level, white blood cell, neutrophil, monocyte and platelet counts with a concomitant decrease in peripheral blood and bone marrow hairy cells. Responding patients also exhibited a marked reduction in red blood cell and platelet transfusion requirements, a decrease in infectious episodes and improvement in performance status. The probability of survival for two years in patients receiving Roferon-A (94%) was statistically increased compared to a historical control group (75%).

ROFERON®-A (Interferon alfa-2a, recombinant/Roche)

INDICATIONS AND USAGE: Roferon-A is indicated for use in the treatment of hairy cell leukemia in people 18 years of age or older. Studies have shown that Roferon-A can produce clinically meaningful regression or stabilization of this disease, both in previously splenectomized and nonsplenectomized patients.[2,3]

Prior to initiation of therapy, tests should be performed to quantitate peripheral blood hemoglobin, platelets, granulocytes and hairy cells and bone marrow hairy cells. These parameters should be monitored periodically (*e.g.*, monthly) during treatment to determine whether response to treatment has occurred. If a patient does not respond within six months, treatment should be discontinued. If a response to treatment does occur, treatment should be continued until no further improvement is observed and these laboratory parameters have been stable for about three months. It is not known whether continued treatment after that time is beneficial. Studies are in progress to evaluate this question.

CONTRAINDICATIONS: Roferon-A is contraindicated in patients with known hypersensitivity to alfa interferon, mouse immunoglobulin or any component of the product.

WARNINGS: Roferon-A should be administered under the guidance of a qualified physician. (See DOSAGE AND ADMINISTRATION.) Appropriate management of the therapy and its complications is possible only when adequate diagnostic and treatment facilities are readily available.

Roferon-A should be used with caution in patients with severe preexisting cardiac disease, severe renal or hepatic disease, seizure disorders and/or compromised central nervous system function.

Because of the possibility of severe or even fatal adverse reactions, patients should be informed not only of the benefits of therapy but also of the risks involved.

Roferon-A should be administered with caution to patients with cardiac disease or with any history of cardiac illness. No direct cardiotoxic effect has been demonstrated, but it is likely that acute, self-limited toxicities (*i.e.*, fever, chills) frequently associated with Roferon-A administration may exacerbate preexisting cardiac conditions. Rarely, myocardial infarction has occurred in patients receiving Roferon-A.

Caution should be exercised when administering Roferon-A to patients with myelosuppression.

Central nervous system adverse reactions have been reported in a number of patients. These reactions included decreased mental status, exaggerated central nervous system function, and dizziness. More severe obtundation and coma have been rarely observed. Most of these abnormalities were mild and reversible within a few days to three weeks upon dose reduction or discontinuation of Roferon-A therapy. Careful periodic neuropsychiatric monitoring of all patients is recommended.

Leukopenia and elevation of hepatic enzymes occurred frequently but were rarely dose-limiting. Thrombocytopenia occurred less frequently. Proteinuria and increased cells in urinary sediment were also seen infrequently. Rarely, significant hepatic, renal and myelosuppressive toxicities were noted.

PRECAUTIONS: *General:* In all instances where the use of Roferon-A is considered for chemotherapy, the physician must evaluate the need and usefulness of the drug against the risk of adverse reactions. Most adverse reactions are reversible if detected early. If severe reactions occur, the drug should be reduced in dosage or discontinued and appropriate corrective measures should be taken according to the clinical judgment of the physician. Reinstitution of Roferon-A therapy should be carried out with caution and with adequate consideration of the further need for the drug and alertness as to possible recurrence of toxicity.

The minimum effective dose of Roferon-A for treatment of hairy cell leukemia has not been established.

Information for Patient: Patients should be cautioned not to change brands of Interferon without medical consultation, as a change in dosage may result. Patients should be informed regarding the potential benefits and risks attendant to the use of Roferon-A. If home use is determined to be desirable by the physician, instructions on appropriate use should be given, including review of the contents of the enclosed Patient Information Sheet. Patients should be well hydrated, especially during the initial stages of treatment.

Laboratory Tests: Periodic complete blood counts and liver function tests should be performed during the course of Roferon-A treatment. They should be performed prior to therapy and at appropriate periods during therapy. Since responses of hairy cell leukemia are not generally observed for one to three months after initiation of treatment, very careful monitoring for severe depression of blood cell counts is warranted during the initial phase of treatment.

Those patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer should have electrocardiograms taken prior to and during the course of treatment.

Carcinogenesis, Mutagenesis and Impairment of Fertility:

Carcinogenesis: Roferon-A has not been tested for its carcinogenic potential.

Mutagenesis: A. Internal studies—Ames tests using six different tester strains, with and without metabolic activation, were performed with Roferon-A up to a concentration of 1920 µg/plate. There was no evidence of mutagenicity.

Human lymphocyte cultures were treated *in vitro* with Roferon-A at noncytotoxic concentrations. No increase in the incidence of chromosomal damage was noted.

B. Published studies—There are no published studies on the mutagenic potential of Roferon-A. However, a number of studies on the genotoxicity of human leukocyte interferon have been reported.

A chromosomal defect following the addition of human leukocyte interferon to lymphocyte cultures from a patient suffering from a lymphoproliferative disorder has been reported.

In contrast, other studies have failed to detect chromosomal abnormalities following treatment of lymphocyte cultures from healthy volunteers with human leukocyte interferon.

It has also been shown that human leukocyte interferon protects primary chick embryo fibroblasts from chromosomal aberrations produced by gamma rays.

Impairment of Fertility: Roferon-A has been studied for its effect on fertility in Macaca mulatta (rhesus monkeys). Nonpregnant rhesus females treated with Roferon-A at doses of 5 and 25 million IU/kg/day have shown menstrual cycle irregularities, including prolonged or shortened menstrual periods and erratic bleeding; these cycles were considered to be anovulatory. These monkeys returned to a normal menstrual rhythm following discontinuation of treatment.

Drug Interactions: Interactions between Roferon-A and other drugs have not been fully evaluated.

PREGNANCY: *Teratogenic Effects:* Pregnancy Category C. Roferon-A has been shown to demonstrate a statistically significant increase in abortifacient activity in rhesus monkeys when given at approximately 20 to 500 times the human dose. A study in pregnant rhesus monkeys treated with 1, 5 or 25 million IU/kg/day of Roferon-A in their early to midfetal period (days 22 to 70 of gestation) has failed to demonstrate teratogenic activity for Roferon-A. There are no adequate and well-controlled studies in pregnant women.
Nonteratogenic Effects: Dose-related abortifacient activity was observed in pregnant rhesus monkeys treated with 1, 5 or 25 million IU/kg/day of Roferon-A in their early to midfetal period (days 22 to 70 of gestation). A late-fetal period study (days 79 to 100 of gestation) is in progress and as yet there have been no reports of any increased rate of abortion.
Usage in Pregnancy: Safe use in human pregnancy has not been established. Therefore, Roferon-A should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. Information from primate studies showed dose-related menstrual irregularities and an increased incidence of spontaneous abortions. Therefore, fertile women should not receive Roferon-A unless they are using effective contraception during the therapy period.

Male fertility and teratologic evaluations have yielded no significant adverse effects to date.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from Roferon-A, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.
Pediatric Use: Safety and effectiveness in children under 18 years of age have not been established.
ADVERSE REACTIONS: The following data on adverse reactions are based on the subcutaneous or intramuscular administration of Roferon-A as a single agent for the treatment of 63 patients with hairy cell leukemia during investigational trials in the United States.
Flu-like syndromes consisting of fatigue (89%), fever (98%), chills (64%), myalgias (73%) and headache (71%) occurred in the majority of patients and tended to diminish with continuing therapy. Other side effects such as anorexia (46%), nausea (32%), emesis (10%), diarrhea (29%), dizziness (21%), rash (18%), change in taste (13%), dryness or inflammation of the oropharynx (16%), dry skin or pruritus (13%) and weight loss (14%) were observed with moderate frequency. Less commonly, diaphoresis (8%), paresthesias (6%), numbness (6%), partial alopecia (8%), reactivation of herpes labialis (8%), transient impotence (6%) and arthralgias (5%) were also observed. Rarely (<3%), central nervous system effects including decreased mental status, depression, visual disturbances, sleep disturbances and nervousness, as well as cardiac adverse events, including hypertension, chest pain, arrhythmias and palpitations, were reported. Adverse experiences which occurred rarely and may have been related to underlying disease, included epistaxis, bleeding gums, ecchymosis and petechiae. Miscellaneous adverse events, such as night sweats, urticaria, conjunctivitis and inflammation at the site of injection, were also rarely observed.
Roferon-A has also been evaluated for the treatment of many other types of cancer under investigational trials in the United States. These studies generally utilized higher doses (12 to 50 million IU/m^2). All of the previously described adverse reactions which occurred in patients with hairy cell leukemia were also observed in patients receiving higher doses. The incidence of most adverse reactions was similar between the two groups, but tended to be more severe in patients who received higher doses of Roferon-A. Some additional adverse effects which occurred in these patients included confusion (10%), hypotension (6%), lethargy (3%) and edema (3%). Adverse experiences occurring in less than 1% of these patients and observed only in patients with malignancies other than hairy cell leukemia are as follows: *Gastrointestinal*—abdominal fullness, hypermotility and hepatitis; *Central Nervous System*—gait disturbance, poor coordination, hallucinations, syncope, seizures, encephalopathy, psychomotor retardation, coma, stroke, transient ischemic attacks, aphasia, aphonia, dysarthria, dysphasia, forgetfulness, amnesia, sedation, apathy, anxiety, emotional lability, irritability, hyperactivity, involuntary movements, claustrophobia and loss of libido; *Peripheral Nervous System*—muscle contractions; *Cardiovascular*—congestive heart failure, pulmonary edema, myocardial infarction, Raynaud's phenomenon and hot flashes; *Pulmonary*—bronchospasm and tachypnea; *Miscellaneous*—excessive salivation and flushing of skin.
Abnormal Laboratory Test Values: The percentage of patients with hairy cell leukemia or with other types of malignancies who experienced a significant abnormal laboratory test value at least once during their treatment is shown in the following table:

ABNORMAL LABORATORY TEST VALUES

	Hairy Cell Leukemia (n = 63)	Overall Safety Summary[*] (n = 1019)
Hematologic		
Leukopenia	59%	69%
Neutropenia	39%	58%
Thrombocytopenia	42%	42%
Decreased Hemoglobin	36%	6.3%
Decreased Hematocrit	43%	12.5%
Mean Time to Nadir		
WBC	38 days	22 days
Platelets	19 days	17 days
Hepatic		
SGOT	47%	78%
Alkaline Phosphatase	18%	48%
LDH	12%	47%
Bilirubin	1.6%	31%
Renal/Urinary		
BUN	2%	10%
Serum Creatinine	3%	10%
Uric Acid[†]	6%	15%
Proteinuria[†]	10%	25%
Other Chemistry Tests		
Hypocalcemia	10%	51%
Elevated FBS[‡]	33%	39%
Elevated Serum Phosphorus	2%	17%

[*] Patients with hairy cell leukemia are included in this overall summary.
[†] The majority of abnormal uric acid values and proteinuria were of minimal severity. Since these abnormalities are commonly observed in patients with advanced malignancy, it is difficult to ascertain their relationship to Roferon-A treatment.
[‡] Random glucose determination.

Neutralizing antibodies to Roferon-A were detected in approximately 27% of all patients (3.4% for patients with hairy cell leukemia). No clinical sequelae of their presence have been documented thus far. Antibodies to human leukocyte interferon may occur spontaneously in certain clinical conditions (cancer, systemic lupus erythematosus, herpes zoster) in patients who have never received exogenous interferon.[4]
DOSAGE AND ADMINISTRATION: Hairy Cell Leukemia—The induction dose of Roferon-A is 3 million IU daily for 16 to 24 weeks, administered as a subcutaneous or intramuscular injection. Subcutaneous administration is particularly advisable for, but not limited to, thrombocytopenic patients (platelet count <50,000) or for patients at risk for bleeding. The recommended maintenance dose is 3 million IU, three times per week. Dosage reduction by one-half or withholding of individual doses may be needed when severe adverse reactions occur. The use of doses higher than 3 million IU is not recommended.
Patients should be treated for approximately six months before the physician determines whether to continue therapy in patients who respond or discontinue therapy in patients who did not respond. Patients with hairy cell leukemia have been treated for up to 20 consecutive months. The optimal duration of treatment for this disease has not been determined.
If severe reactions occur, dosage should be modified (50% reduction) or therapy should be temporarily discontinued until the adverse reactions abate. The need for dosage reduction should take into account the effects of prior X-ray therapy or chemotherapy that may have compromised bone marrow reserve. The minimum effective dose of Roferon-A has not been established.
DIRECTIONS FOR USE: The subcutaneous or intramuscular routes of administration should be used. Subcutaneous administration is particularly suggested for, but not limited to, patients who are thrombocytopenic (platelet count <50,000) or who are at risk for bleeding.
Injectable Solution:
3 million IU Roferon-A per vial—Each 1 mL contains 3 million IU of Interferon alfa-2a, recombinant/Roche, 9 mg sodium chloride for isotonicity, 5 mg human serum albumin as a stabilizer and 3 mg phenol as a preservative.
18 million IU Roferon-A per vial (for multiple-dose use)—Each 1 mL contains 6 million IU of Interferon alfa-2a, recombinant/Roche, 9 mg sodium chloride for isotonicity, 5 mg human serum albumin as a stabilizer and 3 mg phenol as a preservative. Each 0.5 mL contains 3 million IU of Interferon alfa-2a, recombinant/Roche.
The injectable solution should be stored in the refrigerator at 36° to 46°F (2° to 8°C). Do *not* freeze. Do not shake.
Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.
HOW SUPPLIED: Sterile Roferon-A is supplied as single and multiple-dose vials:
Roferon-A Injectable Solution: Vials containing 3 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/mL). Boxes of 10 (NDC 0004-1987-01).
Roferon-A Injectable Solution: Multiple-dose vials containing 18 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/0.5 mL). Boxes of 1 (NDC 0004-1988-09).

RED CELL METABOLISM

A MANUAL OF BIOCHEMICAL METHODS

Third Edition

ERNEST BEUTLER, M.D.

This third edition of **Red Cell Metabolism: A Manual of Biochemical Methods** presents a detailed discussion of the methods required for the measurement of red cell enzymes and metabolic intermediates. The techniques described—which have evolved after years of performing these assays in a laboratory environment—are essential both to the clinical diagnosis of certain types of anemia and to basic research on red blood cells. Topics covered include the fundamentals of handling blood samples, methods of reagent preparation, instrumentation, and calculation of results. New methods, improved procedures, and the increasing importance of certain red cell constituents such as GSH-S-transferase, superoxide dismutase, Na^+-K^+-ATPase, phosphoglycolate phosphatase, and creatine are among the factors that have brought about the need for this updated edition of the text.

Written for hematologists, clinical pathologists, biochemists, and cellular biologists, the third edition of **Red Cell Metabolism** represents the most authoritative and current information in the field of red cell enzymology, and is internationally recognized as the classic text on the subject.

CONTENTS:

Introduction: Purpose and Organization of the Manual. Red Cell Metabolism. **Basic Techniques and Equipment:** The Preparation of Red Cells for Assay. Reagents. Instrumentation. Calculation of Results. **Red Cell Glycolytic Enzymes:** Hexokinase (Hx). Glucose Phosphate Isomerase (GPI). Phosphofructokinase (PFK). Aldolase. Triose Phosphate Isomerase (TPI). Glyceraldehyde Phosphate Dehydrogenase (GAPD). Phosphoglycerate Kinase (PGK). Diphosphoglycerate Mutase (DPGM). Monophosphoglyceromutase (MPGM). Enolase. Pyruvate Kinase (PK). Lactate Dehydrogenase (LDH). **Red Cell Hexose Monophosphate Shunt and Other Enzymes:** Glucose-6-Phosphate Dehydrogenase (G-6-PD) and 6-Phosphogluconate Dehydrogenase (6-PGD). Glutathione Reductase (GR). Glutathione Peroxidase (GSH-Px). Glutathione S-Transferase. NADPH Diaphorase. NADH Methemoglobin Reductase (NADH-Ferricyanide Reductase). Superoxide Dismutase. Phosphoglucomutase (PGM). Glutamate-Oxaloacetate Transaminase (GOT). Phosphoglycolate Phosphatase. Adenylate Kinase (AK). Na^+-K^+ATPase and Mg^{++}ATPase. Adenosine Demmainase (AD). Pyrimidine 5′ Nucleotidase. Acetylcholinesterase. Catalase. Galactose-1-Phosphate Uridyl Transferase. Galactokinase (GK). UDP Glucose-4-Epimerase (Epimerase). **Intermediate Compounds:** ATP. AMP and ADP. 2,3-Diphosphoglycerate (2,3-DPG). Reduced Glutathione (GSH). Oxidized Glutathione (GSSG). Creatine. Glucose. Pyruvate. Lactate. Glucose-6-P and Fructose-6-P. Glyceraldehyde-3-P (GAP), Dihydroxyacetone-P (DHAP), and Fructose-DiP (FDP). 3-Phosphoglyceric Acid (3-GPA). 2-Phosphoglyceric Acid (2-PGA) and Phosphoenolpyruvate. **Screening Techniques:** General Principles. Glucose Phosphate Isomerase Screening Test. Triose Phosphate Isomerase Screening Test. Pyruvate Kinase Screening Test. Glucose-6-Phosphate Dehydrogenase Screening Test. Glutathione Reductase Screening Test. NADH Methemoglobin Reductase (NADH Diaphorase). Pyrimidine 5′ Nucleotidase Screening Test. **Appendix 1:** Activities of Red Cell Enzymes in Normal Adults. **Appendix 2:** Effect of Temperature on Red Cell Enzyme Assays. **Appendix 3:** Levels of Intermediates in Red Cells of Normal Adults. **Appendix 4:** Frequently Used Molecular Weights.

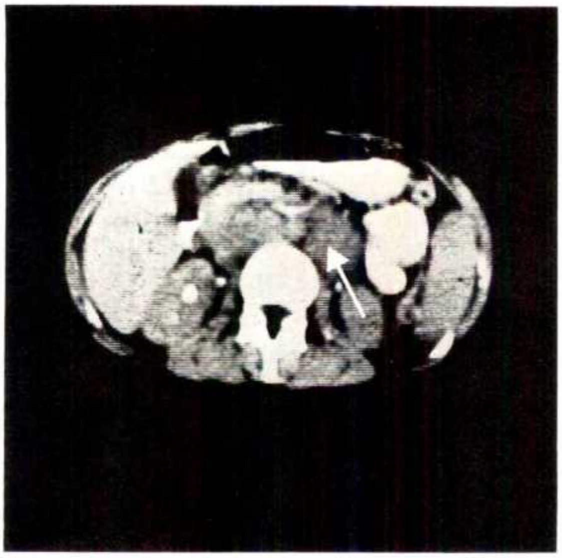
Blenoxane® Combinations

(sterile bleomycin sulfate)

Proven Effective in Non-Hodgkin's Lymphoma

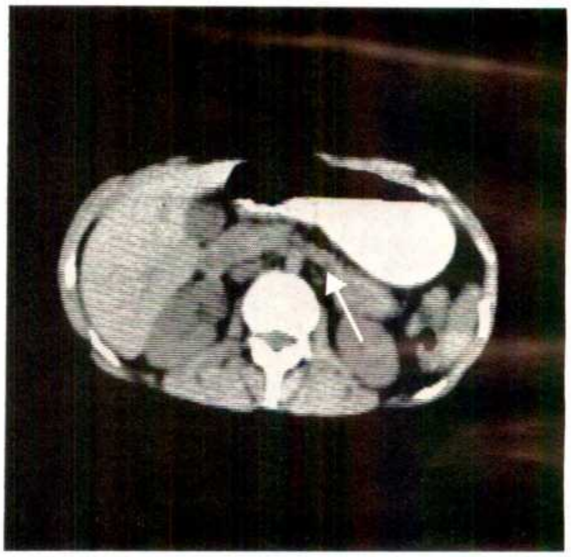
The newer Blenoxane containing combinations resulted in high complete response rates and extended disease-free survival.[1-7]

Abdominal/Pelvic CT
February 25



Massive retroperitoneal, retrocrural, para-aortic, and probable right iliac adenopathy.

Abdominal/Pelvic CT
August 4



No evidence of abnormal abdominal or pelvic adenopathy after Blenoxane combination chemotherapy.

CHOP-Bleo

1. Newcomer LN, Cadman EC, Nerenberg MI, *et al:* Randomized study comparing doxorubicin, cyclophosphamide, vincristine, methotrexate with leucovorin rescue, and cytarabine (ACOMLA) with cyclophosphamide, doxorubicin, vincristine, prednisone, and bleomycin (CHOP-B) in the treatment of diffuse histiocytic lymphoma. *Cancer Treat Rep* 66:1279-1284, 1982.

BACOP

Blenoxane® ...Integral Component of Chemotherapy Regimens in Non-Hodgkin's Lymphoma

(sterile bleomycin sulfate)

Since Blenoxane is virtually non-myelosuppressive, continuing therapy with certain Blenoxane containing chemotherapy regimens (e.g. BACOP) can prevent tumor regrowth between cycles of other chemotherapy regimens while allowing for bone marrow recovery.[*2,3,4,6]

Blenoxane can produce, with cumulative doses, a syndrome of pulmonary fibrosis. It is usually dose-related, being seen infrequently in patients whose total dose of Blenoxane is less than 400 units.

Efficacy... Yesterday, Today, Tomorrow

Blenoxane®
(sterile bleomycin sulfate)

Blenoxane® *(sterile bleomycin sulfate)*

Brief Summary of Prescribing Information (1) 10 84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents.

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: **Pulmonary** – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{co}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{co} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{co} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain $FI\ O_2$ at concentrations approximately that of room air (25%) during surgery and the postoperative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

GAMMAGARD®

Immune Globulin Intravenous (Human)

Today, ours is the only IGIV *not contraindicated* in selective IgA deficiency.

Some patients who need intravenous gamma globulin therapy cannot tolerate IgA. Life-threatening anaphylactic reactions have resulted from infusion of immune globulin containing only *15 micrograms of IgA per milliliter.** Our response: A DEAE-Sephadex adsorption step is included in the GAMMAGARD® IGIV manufacturing process; this removes most non-IgG proteins and IgA.

Result: IgA levels in GAMMAGARD® IGIV are very low; radioimmunoassay test results for six randomly selected lots range between *0.27 and 1.55 micrograms/ml.* This degree of purity greatly reduces the risk of side reactions, particularly for highly sensitive patients. On-going studies (as reported in *The New England Journal of Medicine**), indicate that patients with long histories of IgA-related anaphylaxis tolerate GAMMAGARD® IGIV well. IGIV should still be given with caution in these patients.

The "second-generation" process used to produce GAMMAGARD® IGIV is responsible for its excellent therapeutic characteristics. For example, GAMMAGARD® IGIV retains full native antibody activities, as well as the normal distribution of IgG subclasses.

When your immunocompromised patients require protection, think of GAMMAGARD® IGIV–the IGIV with very low levels of IgA, high levels of purified IgG monomer, and remarkably high titers for an impressive variety of pathogens–in short the IGIV with the purity, safety and efficacy your patients must have.

Artist's conception of DEAE-Sephadex adsorption

DIRECTION INSERT

Immune Globulin Intravenous (Human)
GAMMAGARD®

DESCRIPTION

Immune Globulin Intravenous (Human), GAMMAGARD® * is a sterile, dried, highly purified preparation of immunoglobulin which is derived from the cold ethanol fractionation process and is further purified using ultrafiltration and ion exchange adsorption. When reconstituted with the appropriate volume of diluent, this preparation contains approximately 50 mg of protein per mL, of which at least 90% is gamma globulin. The reconstituted product contains approximately 1% sodium chloride, not more than 20 mg/mL glucose, not more than 0.2 g/dL PEG, and 0.3M glycine as a stabilizing agent. It has a pH of 6.8±0.4.

The manufacturing process for Immune Globulin Intravenous (Human), GAMMAGARD, isolates gamma globulin without additional chemical or enzymatic modification and the Fc portion is maintained intact. Immune Globulin Intravenous (Human), GAMMAGARD contains all the immunoglobulin G antibody activities which are present in the donor population. On the average, the distribution of IgG subclasses present in this product is the same as is present in normal plasma.[1] Immune Globulin Intravenous (Human), GAMMAGARD contains only trace amounts of IgM and IgA.

Immune Globulin Intravenous (Human), GAMMAGARD contains no preservative.

This product has been prepared from large pools of human plasma which was taken only from plasma units found to have normal levels of alanine aminotransferase (ALT). Each unit of plasma used in the manufacture of this product has been found to be nonreactive for HBsAg and HTLV-III antibody by FDA approved tests.

CLINICAL PHARMACOLOGY

Immune Globulin Intravenous (Human), GAMMAGARD contains a broad spectrum of IgG antibodies against bacterial and viral agents that are capable of opsonization and neutralization of microbes and toxins.

Peak levels of IgG are reached immediately after infusion of Immune Globulin Intravenous (Human), GAMMAGARD. It has been shown that IgG is distributed relatively rapidly between plasma and extravascular fluid until approximately half of the total body pool is partitioned in the extravascular space. A rapid initial drop in serum levels is, therefore, to be expected.[2]

As a class, IgG survives longer *in vivo* than other serum proteins.[2,3] Studies show that the half-life of Immune Globulin Intravenous (Human), GAMMAGARD is approximately 24 days. These findings are consistent with reports of a 21 to 25 day half-life for IgG.[2,3,4] The half-life of IgG can vary considerably from person to person, however. In particular, high concentrations of IgG and hypermetabolism associated with fever and infection have been seen to coincide with a shortened half-life of IgG.[2,3,4,5]

INDICATIONS AND USAGE

Antibody Deficiency

Immune Globulin Intravenous (Human), GAMMAGARD is efficacious in the treatment of primary immunodeficient states in which severe impairment of antibody forming capacity has been shown, such as: congenital agammaglobulinemias, common variable immunodeficiency, Wiskott-Aldrich syndrome, and severe combined immunodeficiencies.[4,5]

Immune Globulin Intravenous (Human), GAMMAGARD is especially useful when high levels or rapid elevation of circulating gamma globulins are desired or when intramuscular injections are contraindicated.

CONTRAINDICATIONS

None known.

WARNINGS

Immune Globulin Intravenous (Human), GAMMAGARD should only be administered intravenously. Other routes of administration have not been evaluated.

Immune Globulin Intravenous (Human), GAMMAGARD contains very low quantities of IgA (not more than 10 μg/mL) and although no instances of anaphylaxis associated with the use of this product have been observed during the clinical trials, such reactions have been observed with other immunoglobulin products.[5,6] Immune Globulin Intravenous (Human), GAMMAGARD should be given with caution to patients with antibodies to IgA or selective IgA deficiencies.

PRECAUTIONS

Drug Interaction

Admixtures of Immune Globulin Intravenous (Human), GAMMAGARD with other drugs have not been evaluated. It is recommended that Immune Globulin Intravenous (Human), GAMMAGARD be administered separately from other drugs or medication which the patient may be receiving.

Pregnancy Category C

Animal reproduction studies have not been conducted with Immune Globulin Intravenous (Human), GAMMAGARD. It is also not known whether Immune Globulin Intravenous (Human), GAMMAGARD can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Immune Globulin Intravenous (Human), GAMMAGARD should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

The incidence of untoward reactions to Immune Globulin Intravenous (Human), GAMMAGARD is low, although various minor reactions, such as headache, fatigue, chills, backache, lightheadedness, fever and nausea may occasionally occur. The incidence of these reactions during the clinical trials was less than 6%. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Immediate anaphylactic and hypersensitivity reactions due to previous sensitization, although they have not been observed during the clinical trials, are a possibility. Epinephrine should be available for treatment of any acute anaphylactoid reaction. (See WARNINGS.)

DOSAGE AND ADMINISTRATION

Antibody Deficiency

For patients with primary immunodeficiencies, monthly doses of at least 100 mg/kg are recommended. Initially, patients may receive 200-400 mg/kg. As there are significant differences in the half-life of IgG among patients with primary immunodeficiencies, the frequency and amount of immunoglobulin therapy may vary from patient to patient. The proper amount can be determined by monitoring clinical response and/or the serum IgG levels before each dose, to insure that they do not drop below 500 mg/dL.

Rate of Administration

It is recommended that initially a rate of 0.5 mL/kg per Hr be used. If infusion at this rate causes the patient no distress, the administration rate may be gradually increased but should not exceed 4 mL/kg per Hr.

A rate of administration which is too rapid may cause flushing and changes in pulse rate and blood pressure. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Administration

Immune Globulin Intravenous (Human), GAMMAGARD should be administered as soon after reconstitution as possible. Administration should not begin more than 2 hours after reconstitution.

The reconstituted material should be at room temperature during administration.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Follow directions for use which accompany the administration set. If a Hyland set is not used, make sure the administration set contains an adequate filter.

How Supplied

Immune Globulin Intravenous (Human), GAMMAGARD is supplied in either 2.5 g or 5.0 g single use vials. Each vial of Immune Globulin Intravenous (Human), GAMMAGARD is furnished with a suitable volume of Sterile Water for Injection, USP, a transfer device and an administration set which contains an integral airway and a 15 micron filter.

Storage

Immune Globulin Intravenous (Human), GAMMAGARD should be stored under ordinary refrigeration, (2 to 8 °C, 36 to 46 °F). Freezing should be avoided to prevent the diluent bottle from breaking.

LIQUID NATIVE IGIV…PURE AND SIMPLE

NEW NATIVE IGIV

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 40% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune N equals or exceeds the three week half life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N is 16.5 mEq/L (~0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune N. It is not known whether Gamimune N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune N. Symptoms reported with Gamimune N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1986, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $30.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus.* (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

HERPES SIMPLEX INFECTION IN THE COMPROMISED HOST:

OFTEN SERIOUS, TOO OFTEN UNSUSPECTED

Number one in a series of typical case presentations.

Esophagitis in a leukemia patient

In patients with hematologic malignancies, the visceral organ most frequently involved by herpes simplex virus (HSV) infection is the esophagus.[1] Extensive ulcerative lesions may develop on the upper two thirds of the esophagus with confluent lesions of the distal third.[2] In some cases, however, the mucosa may be grossly unremarkable even when microscopic examination shows evidence of herpetic ulcerative esophagitis.[1] Similarly, some patients may display symptoms of dysphagia and burning retrosternal pain,[3] whereas others may appear asymptomatic.[1] The diagnostic method of choice for patients with suspected herpetic esophagitis is esophagoscopy with visualization of the mucosa and procurement of cytologic and biopsy specimens from ulcerated areas.[1]

Herpetic infections may result in extensive disease and death

Immunocompromised patients are highly vulnerable to HSV infection. Such infections may interrupt therapy and even lead to death if not detected early and managed aggressively.[1] Although the initial appearance may be mild, HSV infection may progress to severe localized mucocutaneous ulcerations. The greatest threat that herpes simplex poses is an infection that disseminates from a mucocutaneous or unrecognized primary lesion and involves the lungs, liver, esophagus, or central nervous system.[1] Furthermore, herpetic ulcers frequently provide an entry for secondary bacterial and fungal pathogens.[2]

Infections may not be diagnosed correctly without virologic study

Some investigators claim that the actual incidence of serious HSV infection is probably higher than reported because "the possibility of herpetic disease is insufficiently considered and appropriate diagnostic viral studies are often not carried out."[3] One study, for example, found histocytologic evidence of visceral herpes infection in 56 patients even though herpetic involvement was not suspected in any of the patients prior to autopsy.[2]

ZOVIRAX I.V. halts viral replication and speeds healing even in debilitated patients

ZOVIRAX I.V. has been shown to be a highly effective treatment for severe mucocutaneous HSV infection in immunocompromised patients. In controlled trials, ZOVIRAX I.V. rapidly halted viral shedding — within 3 days in most patients — and significantly shortened healing time as well as duration of pain.[4,5] Furthermore, ZOVIRAX I.V. may allow patients to return home sooner and enable patients with intraoral lesions to resume normal eating habits.[6]

ZOVIRAX I.V. is well tolerated by immunocompromised patients

A multicenter collaborative trial of ZOVIRAX I.V. in immunocompromised patients reported that: "Clinical benefits were obtained without appreciable toxicity. The most common reactions were irritation of peripheral veins used for drug infusion and a low incidence of rash.... Significant renal or hematologic toxicity did not occur, even in these seriously ill patients who were commonly receiving other drugs concomitantly."[5]

Note: Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes. Please see brief summary for more information.

An effective response to a life-threatening infection
ZOVIRAX® I.V. INFUSION
(acyclovir sodium) sterile powder

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M² every 8 hours (750 mg/M²/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously, or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M²) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS*** — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M² at a constant rate over 1 hour, every 8 hours (750 mg/M²/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M²)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

Introducing....
SEPRACELL-MN®

The most advanced technology in mononuclear cell separation from whole blood.

You demand performance and quality in the products used in immunology today. Yet, density media products for lymphocyte separation provided few choices in performance and quality—until now.

Sepracell-MN is a colloidal silica based medium for the separation of mononuclear cells from whole blood by *continuous* density gradient centrifugation.

PERFORMANCE

80%	lymphocyte recovery	75%	lymphocyte purity
98%	viability	20%	monocytes

QUALITY

Sepracell-MN is sterile and non-toxic for functional studies. Results are included with each lot for lymphocyte recovery, purity, T and B cell ratios, and mitogen response.

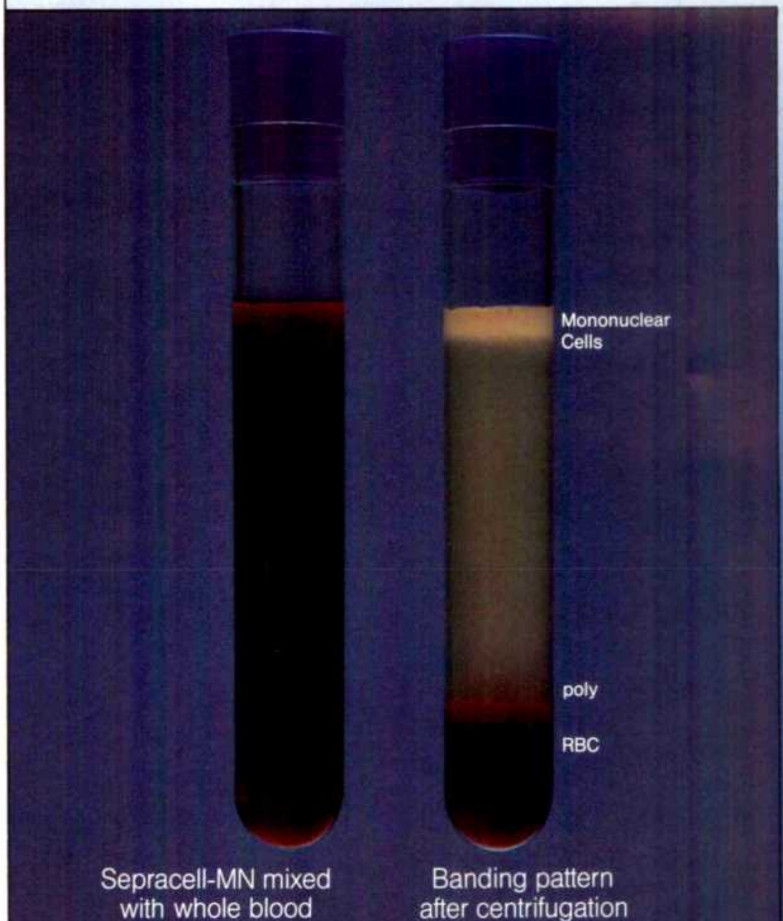
CONVENIENT

Available in prepackaged racks of 50 sterile centrifuge tubes for whole blood separation.

ECONOMICAL

Prepackaged sterile tubes eliminate waste of separation media and use of expensive sterile centrifuge tubes. Quick separations and consistently greater lymphocyte recoveries reduces the time, blood, and supplies required for lymphocyte separations.

For in vitro diagnostic use. Patent Pending.



Sepracell-MN mixed with whole blood

Banding pattern after centrifugation
(2,000 x G 10 min.)

Easy to use

No layering or dilution of blood. Just add whole blood (up to 6 mls.) to the prepackaged tube, mix and spin for 10 minutes.

CALL TOLL FREE
1-800-222-0924 for Free Samples (10 prepackaged tubes).
1-800-222-0924 for Ordering

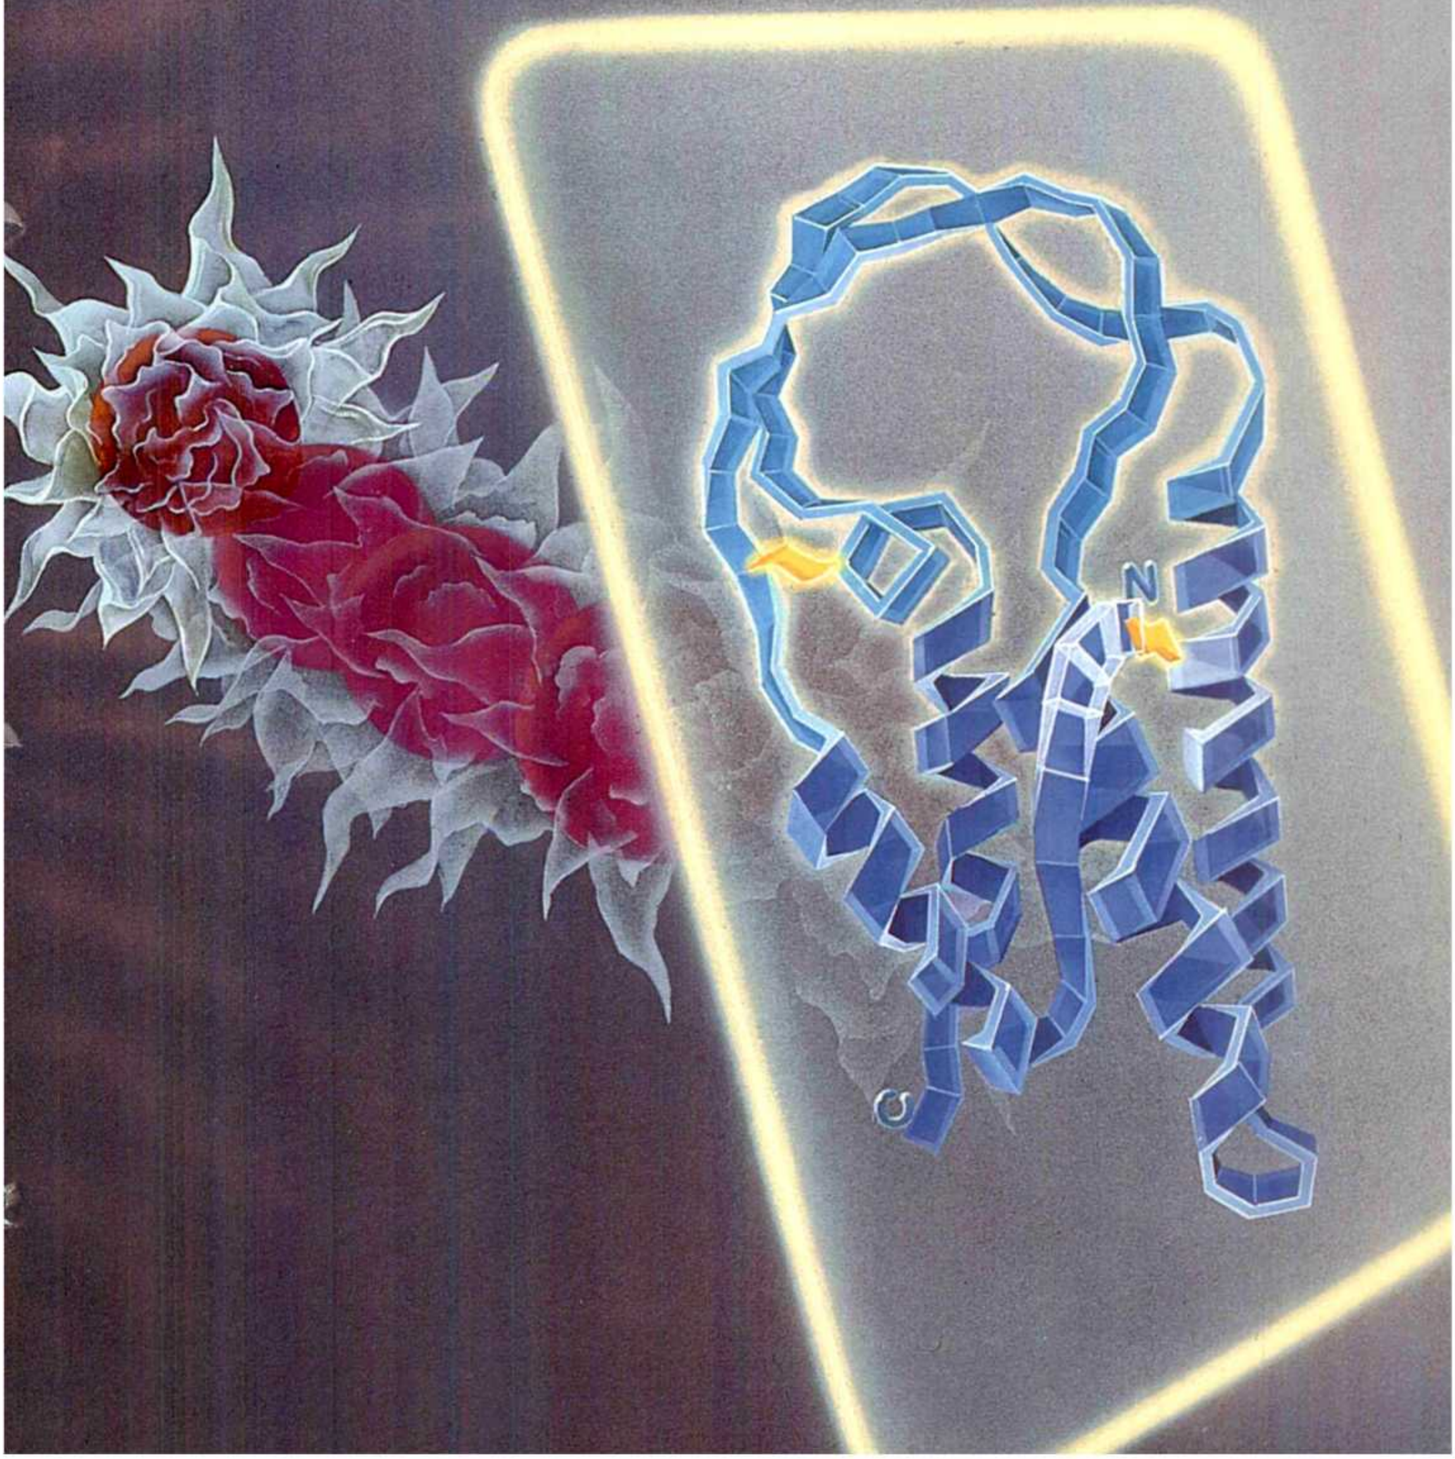
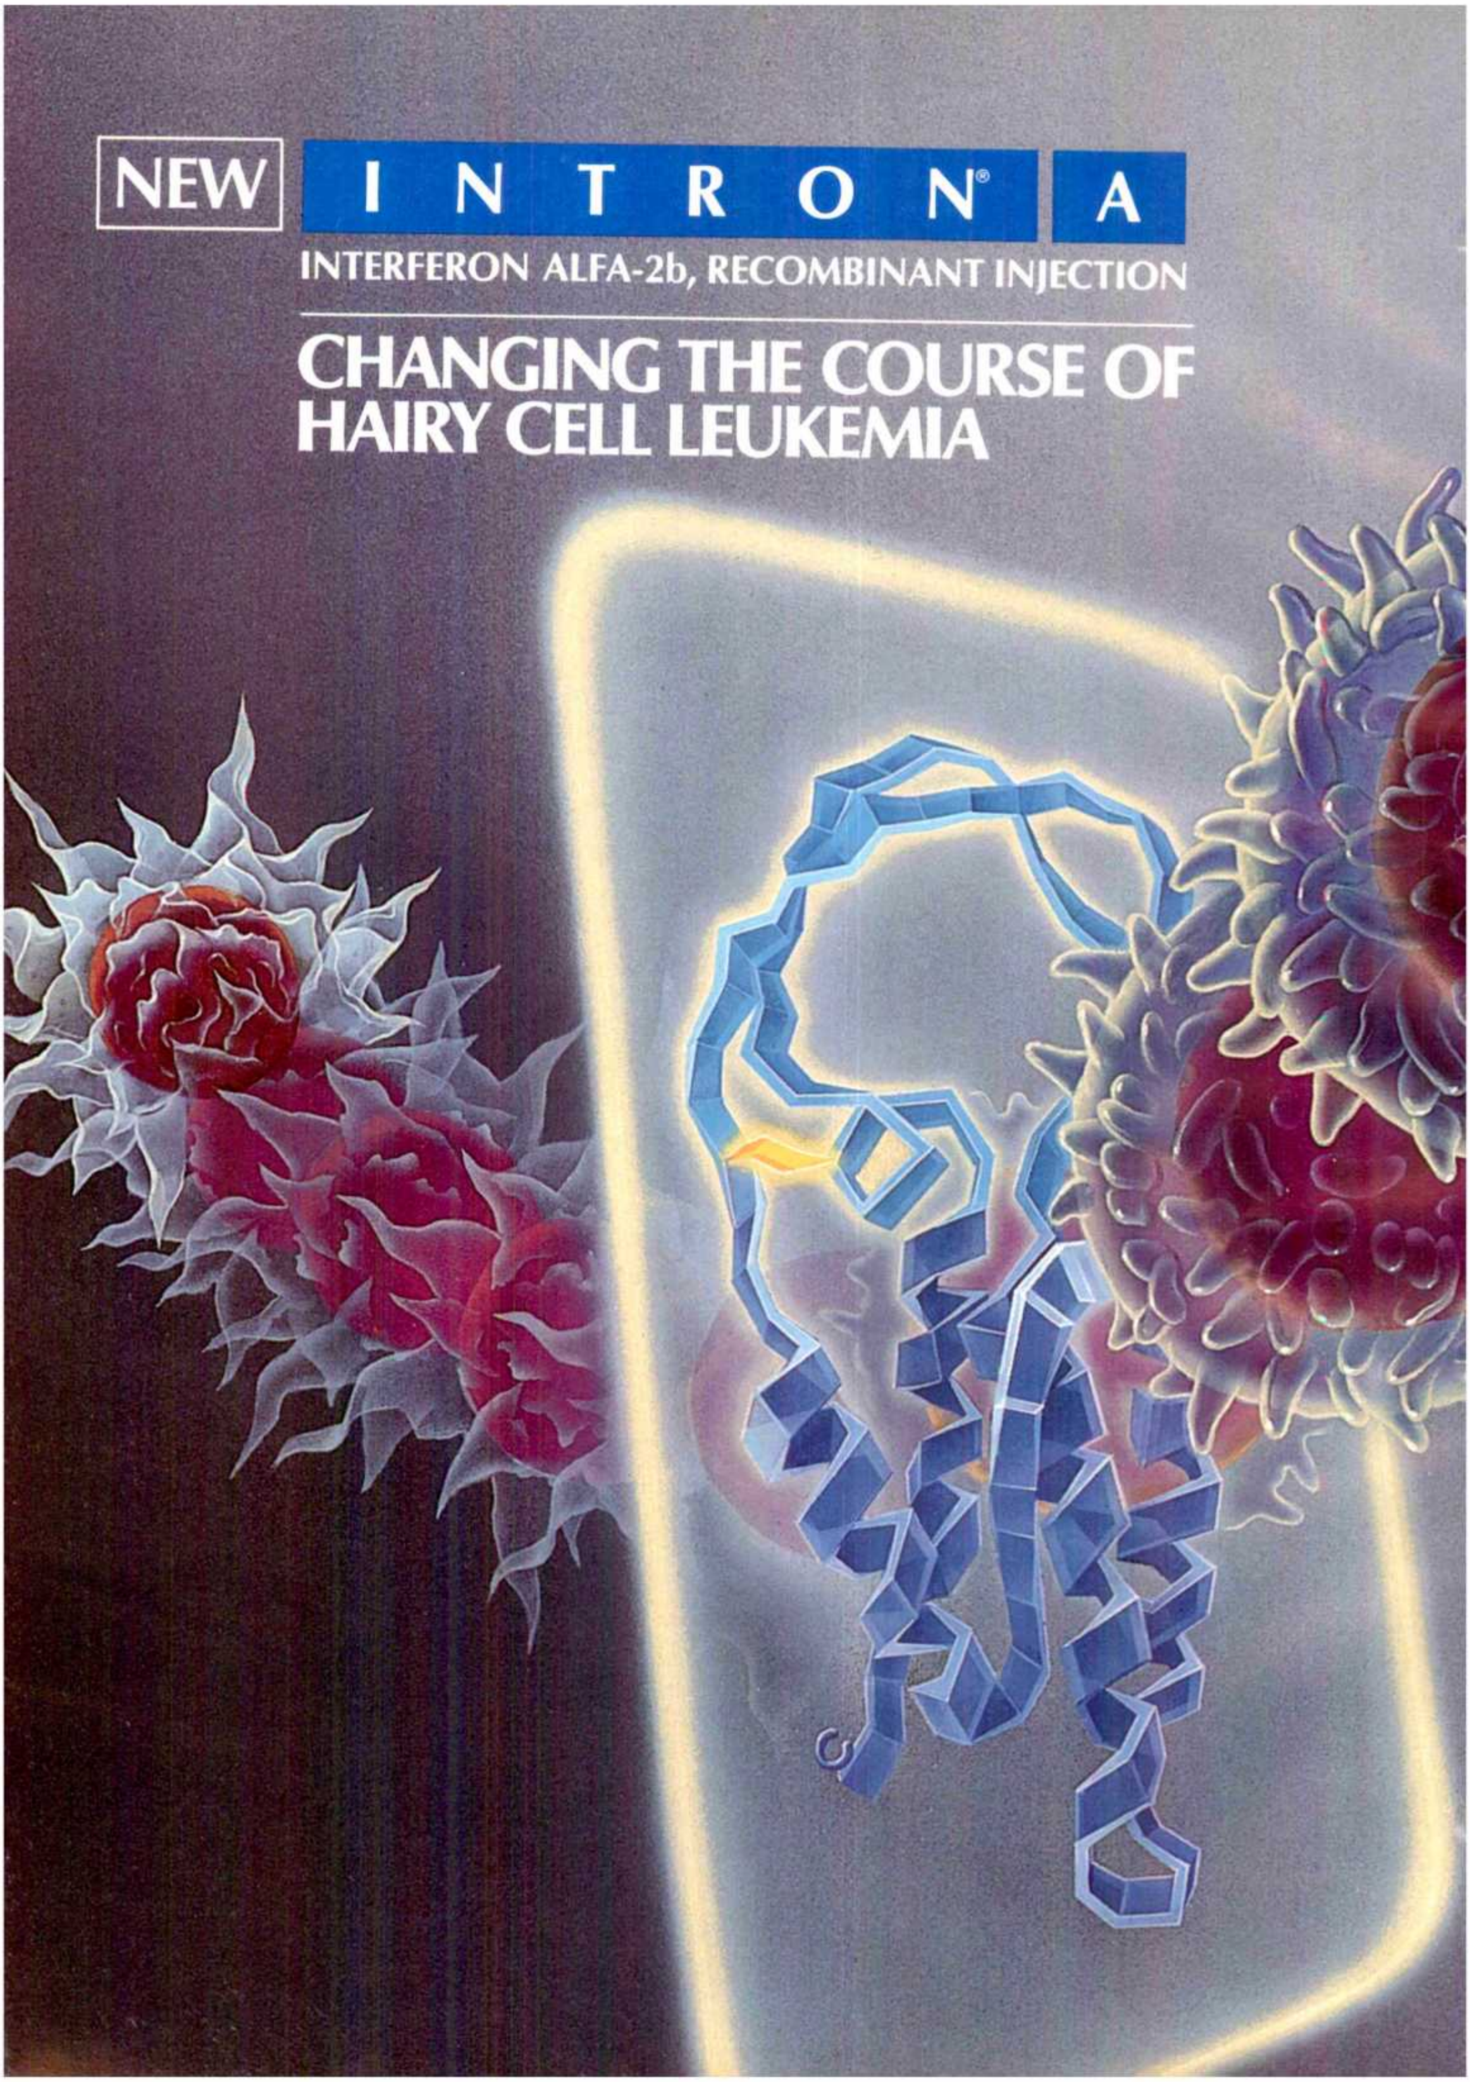
FROM ADVANCES IN BIOTECHNOLOGY...

NEW INTRON® A

INTERFERON ALFA-2b, RECOMBINANT INJECTION

THE FIRST INTERFERON
FROM SCHERING RESEARCH

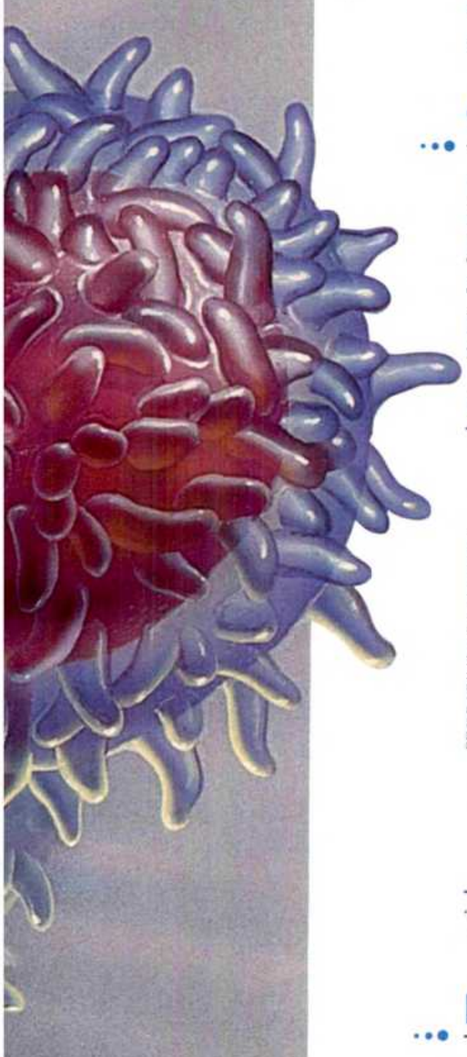




NEW INTRON® A

INTERFERON ALFA-2b, RECOMBINANT INJECTION

CHANGING THE COURSE OF HAIRY CELL LEUKEMIA



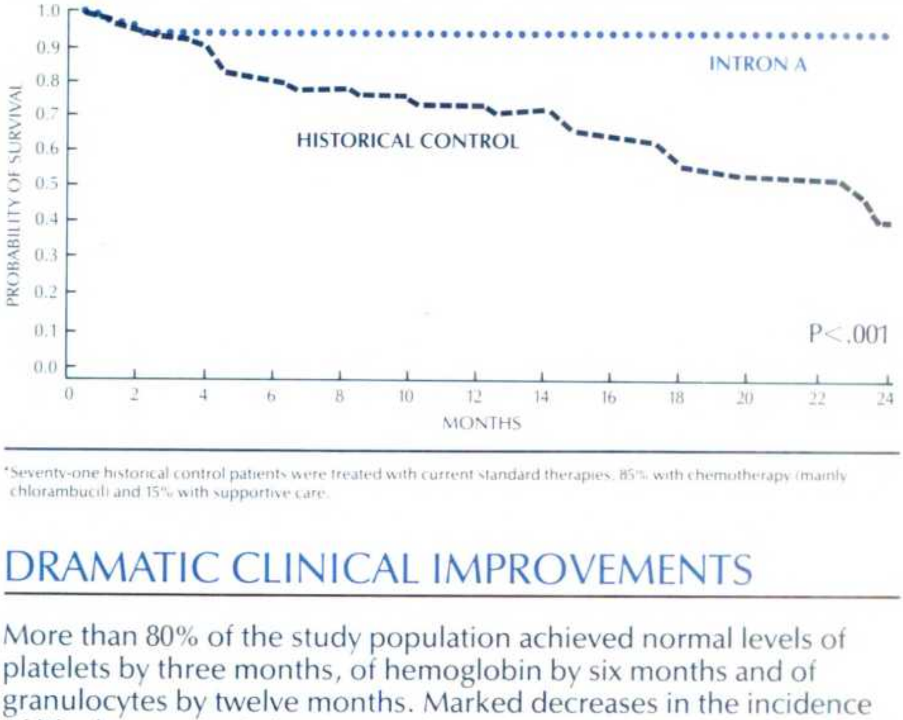
EFFICACY WELL ESTABLISHED

The efficacy of INTRON A was established in a 26-center clinical trial of 145 patients with progressive hairy cell leukemia, a B-cell malignancy.[1,2,3] INTRON A achieved a 74% objective response, measured as normalization of granulocyte, hemoglobin and platelet values and elimination of transfusion dependency.[1]

92% PROBABILITY OF SURVIVAL

In a separate analysis, a 24-month comparison was conducted between the INTRON A study population and historical controls.* After three months of therapy, patients receiving INTRON A reached and maintained a plateau of 92% probability of survival. The probability of survival among historical controls, however, declined steadily to 40% at 24 months.[1]

KAPLAN–MEIER ESTIMATED SURVIVAL CURVES



*Seventy-one historical control patients were treated with current standard therapies: 85% with chemotherapy (mainly chlorambucil) and 15% with supportive care.

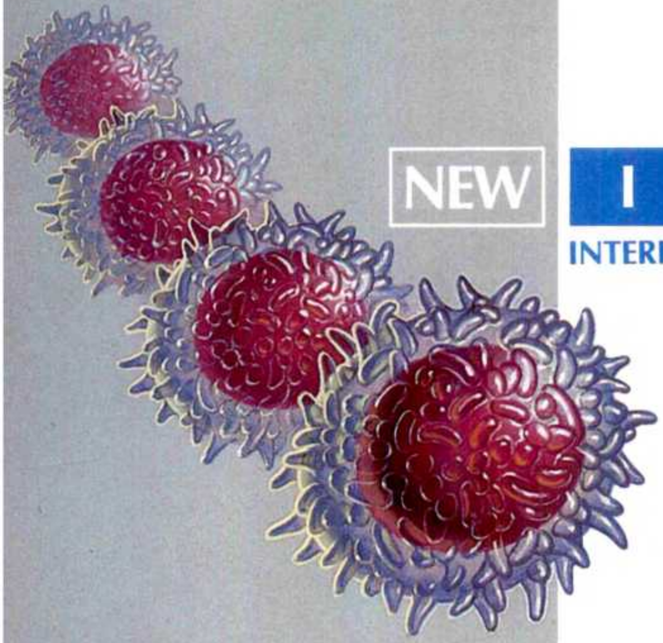
DRAMATIC CLINICAL IMPROVEMENTS

More than 80% of the study population achieved normal levels of platelets by three months, of hemoglobin by six months and of granulocytes by twelve months. Marked decreases in the incidence of life-threatening infections and transfusion dependency preceded normalization of hematologic values.[1]

THERAPY WELL TOLERATED

Treatment-related side effects were generally mild to moderate and rapidly reversible upon discontinuation of therapy. The predominant complaint was a flu-like syndrome, which usually diminished with continued therapy. Mild-to-moderate skin rashes occurred intermittently in 40% of the study population. A low incidence of mild-to-moderate GI disorders was also reported.[1]

For a brief summary of prescribing information, please see the following page.



NEW **INTRON® A**

INTERFERON ALFA-2b, RECOMBINANT INJECTION

A NEW CLASS OF CANCER THERAPY

A BIOLOGIC RESPONSE MODIFIER

To date, interferon actions in experimental systems have not been directly correlated with its clinical efficacy. However, as a biologic response modifier, interferon may modulate the immune system,[4,5,6] indirectly affect cell differentiation[7] and phenotypic expression[8,9] and enhance protection against viral infection.[10] In addition, interferon may have antiproliferative activity in experimental systems, seen as oncogene inhibition[11,12] and cytostatic action.[13,14,15]

99% PURITY

INTRON A production utilizes the new biotechnology of genetic engineering and Schering's advanced production process for assured purity.

For more information, please call **1-800-4-INTRON**.

PRODUCT INFORMATION

THE FIRST INTERFERON FROM SCHERING RESEARCH

INTRON® A Interferon alfa-2b recombinant for Injection

BRIEF SUMMARY

INDICATIONS AND USAGE INTRON A for Injection is indicated for the treatment of patients 18 years of age or older with hairy cell leukemia. Studies have shown that INTRON A can produce clinically meaningful regression or stabilization of this disease, both in previously splenectomized and non-splenectomized patients.

Prior to initiation of therapy, tests should be performed to quantitate peripheral blood hemoglobin, platelets, granulocytes and hairy cells and bone marrow hairy cells. These parameters should be monitored periodically during treatment to determine whether response to treatment has occurred. If a patient does not respond within 6 months, treatment should be discontinued. If a response to treatment does occur, treatment usually should be continued until no further improvement is observed and these laboratory parameters have been stable for about 3 months (see **DOSAGE AND ADMINISTRATION**). It is not known whether continued treatment after that time point is beneficial. Studies are in progress to evaluate this question.

CONTRAINDICATIONS INTRON A is contraindicated in patients with a history of hypersensitivity to interferon alfa or any component of the injection.

WARNINGS Moderate to severe adverse experiences may require modification of the patient's dosage regimen, or in some cases, termination of therapy with INTRON A.

Because of the fever and other "flu-like" symptoms associated with INTRON A administration, it should be used cautiously in patients with debilitating medical conditions, such as those with a history of cardiovascular disease (e.g., unstable angina, uncontrolled congestive heart failure), pulmonary disease (e.g., chronic obstructive pulmonary disease), or diabetes mellitus prone to ketoacidosis. Caution should also be observed in patients with coagulation disorders (e.g., thrombophlebitis, pulmonary embolism) or severe myelosuppression.

Patients with platelet counts of less than $50{,}000/mm^3$ should not be administered INTRON A intramuscularly, but instead by subcutaneous administration.

Cardiovascular adverse experiences which include significant hypotension, arrhythmia, or tachycardia of 150 beats per minute or greater, were observed in approximately 3% of the patients studied who had various malignancies and were treated at doses higher than those for hairy cell leukemia. The incidence of these complications in patients with preexisting heart disease is unknown. Hypotension may occur during administration, or up to two days post therapy, and may require supportive therapy including fluid replacement to maintain intravascular volume. Supraventricular arrhythmias occurred rarely and appeared to be correlated with preexisting conditions, and prior therapy with cardiotoxic agents. These adverse experiences were controlled by modifying the dose or discontinuing treatment, but may require specific additional therapy.

Those patients with a recent history of myocardial infarction and/or previous or current arrhythmic disorder, who require INTRON A therapy, should be closely monitored (see **Laboratory Tests**).

Central nervous system effects manifested by depression, confusion and other alterations of mental status were observed in about 2% of hairy cell leukemia patients treated with INTRON A. The overall incidence in a larger patient population with other malignancies treated with higher doses of INTRON A was 10%. More significant obtundation and coma have been observed in some patients, usually elderly, treated at higher doses for other malignant diseases. These effects are usually rapidly reversible. In a few severe episodes, full resolution of symptoms has taken up to three weeks. Patients should be closely monitored until resolution of these effects. Discontinuation of INTRON A Interferon alfa-2b, recombinant for Injection therapy may be required. Narcotics, hypnotics, or sedatives may be used concurrently with caution.

Acute serious hypersensitivity reactions (e.g., urticaria, angioedema, bronchoconstriction, anaphylaxis, etc.) have not been observed in patients receiving INTRON A; however, if such an acute reaction develops, the drug should be discontinued immediately and appropriate medical therapy instituted. Transient cutaneous rashes have occurred in some patients following injection, but have not necessitated treatment interruption.

Laboratory abnormalities which occurred in hairy cell leukemia patients included elevated SGOT and SGPT, which occurred in 4% and 13% of patients, respectively. The overall incidences of laboratory abnormalities in a larger patient population with other malignancies, and treated at higher doses were somewhat higher. These included elevated liver function tests (SGOT, SGPT in 10% of patients) and reductions in granulocyte (20% of patients) and platelet counts (18% of patients) (see **Laboratory Tests**). These abnormalities are usually mild to moderate and transient. Severe abnormalities of these laboratory parameters are usually rapidly reversible upon cessation or reduction of INTRON A therapy.

PRECAUTIONS Information for Patients Patients being treated with INTRON A should be directed in its appropriate use, informed of benefits and risks associated with treatment and referred to the Patient Information Sheet.

Patients should be cautioned not to change brands of Interferon without medical consultation as a change in dosage may result.

It is advised that patients be well hydrated especially during the initial stages of treatment.

Laboratory Tests In addition to those tests normally required for monitoring patients with hairy cell leukemia, the following laboratory tests are recommended for all patients on INTRON A therapy, prior to beginning treatment and then periodically thereafter:

- Standard hematologic tests — including complete blood counts and differential as well as platelet counts.
- Blood chemistries — electrolytes and liver function tests.

Those patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer, should have electrocardiograms taken prior to and during the course of treatment.

Carcinogenesis, Mutagenesis, Impairment of Fertility Studies with INTRON A have not been performed to determine carcinogenicity, or the effect on fertility. Interferon may impair fertility. Mutagenicity studies with INTRON A revealed no adverse effects.

Studies in mice, rats, and monkeys injected with INTRON A for up to one month have revealed no evidence of toxicity. However, due to the known species-specificity of interferon, the effects in animals are unlikely to be predictive of those in man.

Pregnancy Category C Animal reproduction studies have not been conducted with INTRON A. It is also not known whether INTRON A can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. INTRON A should be given to a pregnant woman only if clearly needed. Another interferon alfa preparation has been shown to have abortifacient effects in *Macaca mulatta* (rhesus monkeys) when given at 20 to 500 times the human dose. Therefore, INTRON A should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. In studies of interferon use in non-human primates, abnormalities of the menstrual cycle have been observed.

INTRON A Interferon alfa-2b, recombinant for Injection should be used with caution in fertile men and women.

Nursing Mothers It is not known whether this drug is excreted in human milk. However, studies in mice have shown that mouse interferons are excreted into the milk. Because of the potential for serious adverse reactions from INTRON A in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use Safety and effectiveness have not been established in patients below the age of 18 years.

ADVERSE REACTIONS Adverse reactions to INTRON A are dose-related. In studies of patients with malignancies other than hairy cell leukemia, hematologic and hepatic toxicities were more common in patients receiving individual injections greater than 10 million IU, than in patients receiving less than this amount. Hematologic, hepatic, cardiovascular and neurologic toxicities were more common in patients receiving more than 30 million IU per injection than in patients receiving less than that amount.

The following adverse reactions were reported to be possibly or probably related to INTRON A therapy during clinical trials. The most frequently reported adverse reactions were flu-like symptoms, primarily fever, fatigue, and chills which occurred in almost all patients treated. Other organ systems in which reactions occurred in more than 5% of the patients are:

General — Taste alteration, anorexia and weight decrease occurred uncommonly.

Cardiovascular — Mild hypotension was frequently recorded although it was rarely symptomatic. Hypertension also occurred less commonly. Tachycardias occurred uncommonly usually in association with high fevers.

Gastrointestinal System — Nausea was common, although vomiting occurred rarely. Mild diarrhea was reported less commonly.

Hematologic — Mild thrombocytopenia and transient granulocytopenia occurred commonly.

Musculo-Skeletal System — Myalgia and arthralgia occurred commonly, usually in association with other flu-like symptoms.

Nervous System — Headache, somnolence, confusion, and dizziness occurred uncommonly. Ataxia and paresthesia were rare.

Psychiatric — Anxiety, depression and nervousness occurred uncommonly.

Skin and Appendages — Mild pruritus occurred uncommonly. Mild alopecia was uncommon. Various transient, mild skin rashes were seen frequently in patients with hairy cell leukemia.

Other Adverse Reactions — The following adverse reactions were reported with an incidence of 5% or less: leg cramps, constipation, insomnia, herpetic eruptions, non-herpetic cold sores, urticaria, hot flashes, supraventricular arrhythmias, epistaxis, stomatitis, paralytic ileus, dehydration, coagulation disorder (elevated PT and PTT), abnormal vision, tremor, emotional lability, chest pain, pharyngitis and syncope.

Adverse reactions reported rarely (less than 1%) were dyspepsia, purpura, dyspnea, sneezing, oculomotor paralysis, nasal congestion, flatulence, increased saliva, hyperglycemia, and ulcerative stomatitis.

Laboratory Value Changes — Those patient laboratory values which were normal to moderately abnormal (WHO grades 0–2) at baseline that worsened to either severe or life-threatening abnormalities (WHO grades 3 or 4) during some phase of treatment included: WBC, platelets, granulocytes, SGOT, creatinine, SGPT, LDH, and alkaline phosphatase.

DOSAGE AND ADMINISTRATION The recommended dosage of INTRON A for Injection for the treatment of hairy cell leukemia is 2 million IU/m^2 administered intramuscularly (see **WARNINGS**) or subcutaneously 3 times a week. Higher doses are not recommended. The normalization of one or more hematologic variables usually begins within 2 months of initiation of therapy. Improvement in all three hematologic variables may require 6 months or more of therapy.

This dosage regimen should be maintained unless the disease progresses rapidly, or severe intolerance is manifested. If severe adverse reactions develop, the dosage should be modified (50% reduction) or therapy should be temporarily discontinued until the adverse reactions abate. If persistent or recurrent intolerance develops following adequate dosage adjustment, or disease progresses, treatment with INTRON A Interferon alfa-2b, recombinant for Injection should be discontinued. The minimum effective dose of INTRON A has not been established.

At the discretion of the physician, the patient may self-administer the dose. The medication may be administered at bedtime.

HOW SUPPLIED INTRON A Interferon alfa-2b, recombinant for Injection is available in 3-, 5-, 10- and 25-million IU vials, each packaged with its own diluent.

Store INTRON A for Injection, both before and after reconstitution, between 2° and 8°C (36° and 46°F).

Twenty years ago, leukemia* killed enough people to fill the Houston Astrodome.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

LEUCOVORIN CALCIUM

LEUCOVORIN CALCIUM INJECTION
Military Depot: NSN 6505-01-054-7008,
50 mg/vial for I.M. use

DESCRIPTION: Each 1 ml ampul of Leucovorin Calcium *Lederle* contains Leucovorin 3 mg as the calcium salt which is the form preferred for intramuscular injection. Preservative: benzyl alcohol 0.9% w/v. The inactive ingredients are sodium chloride 0.56% w/v, Water for Injection qs 100% and sodium hydroxide or hydrochloric acid is used to adjust the pH to approximately 7.7.

Each 50 mg vial of Leucovorin Calcium cryodesiccated powder when reconstituted with 5 ml of sterile diluent contains Leucovorin 10 mg per ml as the calcium salt which is the form preferred for intramuscular injection. Contains no preservative. Dilute only with Bacteriostatic Water for Injection USP which contains benzyl alcohol. The inactive ingredients are sodium chloride 40 mg/vial, and sodium hydroxide or hydrochloric acid qs to pH approximately 8.1. When reconstituted as directed, the resulting solution must be used within seven days. If the product is reconstituted with Water for Injection USP, use immediately.

ACTIONS: Leucovorin (folinic acid) is the formyl derivative and active form of folic acid.

Leucovorin Calcium is useful clinically in circumventing the action of folate reductase. There is no evidence that intramuscular doses of greater than 1 mg have greater efficacy than those of 1 mg.

INDICATIONS: Indicated (a) to diminish the toxicity and counteract the effect of inadvertently administered overdosages of folic acid antagonists. (See Warnings) (b) In the treatment of the megaloblastic anemias due to sprue, nutritional deficiency, pregnancy, and infancy when oral therapy is not feasible.

CONTRAINDICATIONS: Not to be administered for the treatment of pernicious anemia or other megaloblastic anemias where Vitamin B_{12} is deficient.

WARNINGS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to lack of Vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

In the treatment of overdosage of folic acid antagonists, Leucovorin must be administered within one hour, if possible, and is usually ineffective if administered after a delay of four hours.

PRECAUTIONS: In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive.

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

DOSAGE: Megaloblastic anemia. No more than or up to 1 mg daily. There is no evidence that intramuscular doses greater than 1 mg daily have greater efficacy than those of 1 mg, additionally, loss of folate in the urine becomes roughly logarithmic as the amount administered exceeds 1 mg.

For the treatment of overdosage of folic acid antagonists. To be given in amounts equal to the weight of the antagonist given.

HOW SUPPLIED:
NDC 0205-4004-51—6—1 ml Ampuls
NDC 0205-5330-92—50 mg Vial of Cryodesiccated powder

LEDERLE PARENTERALS, INC

LEUCOVORIN CALCIUM TABLETS

BRIEF SUMMARY

Before prescribing Leucovorin Calcium Tablets, please consult complete prescribing information.

INDICATIONS AND USAGE: Leucovorin Calcium Tablets are indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (eg, methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS: *General.* Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia, a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy. Teratogenic Effects. Pregnancy Category C. Animal reproduction studies have not been conducted with leucovorin. It is also not known whether leucovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Leucovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when leucovorin is administered to a nursing mother.

Pediatric Use. (See Drug Interactions.)

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for 72 hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the premethotrexate serum creatinine, the leucovorin dosage should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[7,8] The recommended dosage of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (ie, trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[9,10,11]

REVIEW

Immunologic Classification of Leukemia and Lymphoma

By Kenneth A. Foon and Robert F. Todd, III

Important insights into leukocyte differentiation and the cellular origins of leukemia and lymphoma have been gained through the use of monoclonal antibodies that define cell surface antigens and molecular probes that identify immunoglobulin and T cell receptor genes. Results of these studies have been combined with markers such as surface membrane and cytoplasmic immunoglobulin on B lymphocytes, sheep erythrocyte receptors on T lymphocytes, and cytochemical stains. Using all of the above markers, it is now clear that acute lymphoblastic leukemia (ALL) is heterogeneous. Furthermore, monoclonal antibodies that identify B cells, such as the anti-B1 and anti-B4 antibodies in combination with studies of immunoglobulin gene rearrangement, have demonstrated that virtually all cases of non-T-ALL are malignancies of B cell origin. At least six distinct subgroups of non-T-ALL can now be identified. T-ALL is subdivided by the anti-Leu-9, anti-Leu-1, and antibodies that separate T lymphocyte subsets into three primary subgroups. Monoclonal antibodies are also useful in the subclassification of non-Hodgkin's lymphoma, and certain distinct markers can be correlated with morphologic classification. The cellular origin of the malignant Reed-Sternberg cell in Hodgkin's disease remains uncertain. A substantial number of investigators favor a myelocyte/macrophage origin based on cytochemical staining; however, consistent reactivity with antimonocyte reagents has not been demonstrated. Although monoclonal antibodies are useful in distinguishing acute myeloid from acute lymphoid leukemias, they have less certain utility in the subclassification of acute myelogenous leukemia (AML). Attempts to subclassify AML by differentiation-associated antigens rather than by the French-American-British (FAB) classification are underway in order to document the potential prognostic utility of surface markers. Therapeutic trials using monoclonal antibodies in leukemia and lymphoma have been reported. Intravenous (IV) infusion of unlabeled antibodies is the most widely used method; transient responses have been demonstrated. Antibodies conjugated to radionuclides have been quite successful in localizing tumors of <1 cm in some studies. Therapy trials with antibodies conjugated to isotopes, toxins, and drugs are currently planned. Purging of autologous bone marrow with monoclonal antibodies and complement in vitro has been used in ALL and non-Hodgkin's lymphoma; preliminary data suggest that this approach may be an effective therapy and may circumvent many of the obstacles and toxicities associated with in vivo monoclonal antibody infusion.

RECENT ADVANCES in immunology have led to important insights into leukocyte differentiation and the cellular origin of leukemia. It is now possible to define stages of human lymphocyte and granulocyte differentiation precisely using highly specific monoclonal antibodies that define cell surface antigens and molecular probes that identify rearrangement of immunoglobulin and T cell receptor genes. These can be combined with more traditional cell markers such as surface membrane (SmIg) and cytoplasmic immunoglobulin (CIg) on B lymphocytes, sheep erythrocyte receptors on T lymphocytes, and cytochemical stains. In this review, we summarize advances in the classification of leukemia and lymphoma and their importance in our understanding of normal leukocyte differentiation and therapeutic implications.

CELL MARKERS

B lymphocytes. B lymphocytes are usually identified by the presence of SmIg. Progenitors of B lymphocytes, commonly referred to as "pre-B cells," are present in fetal liver and normal bone marrow; the cells display cytoplasmic μ-heavy chain ($C\mu$) but lack intracytoplasmic light chain and SmIg. B and pre-B lymphocytes may also have receptors for the third component of complement (C'3) and for the Fc portion of IgG. Fc and C'3 receptors are not specific for the B cell lineage and are found in other cells such as monocytes and some nonhematopoietic cells. Similarly, histocompatibility-related antigens (Ia or HLA-DR) are also found on the surface of B cells, but are not unique to them.[1-4] Plasma cells are the most mature B lymphocytes; they lack detectable

OKT10	Thymocytes	45	NA	27
Anti-Ta$_1$	Activated T lymphocytes	105	NA	58
Anti-Tac	Interleukin-2 receptor	55	CD25	59–61

NR, not reported, NA, not applicable.

The OKT series of antibodies is available through Ortho Systems, Inc, Raritan, NJ; Leu series through Becton Dickinson Co, Mountainview, Calif; anti-T through Coulter Immunology, Hialeah, Fla; Lyt through New England Nuclear, Boston; and T101 through Hybritech Inc, San Diego.

SmIg but have CIg. Unlike the CIg found in pre-B lymphocytes, CIg in plasma cells includes both heavy and light chains.

A number of heteroantisera and, more recently, monoclonal anitbodies that identify B cell-associated antigens have been described (Table 1).[4-22] Where applicable, the nomenclature and clusters of differentiation (CD) defined by the Second International Workshop on Human Leukocyte Differentiation Antigens are shown.[23-25]

T lymphocytes. T lymphocytes were initially identified by their ability to bind sheep erythrocytes spontaneously. T lymphocytes also react with T cell-specific antisera and anti-T cell monoclonal antibodies, which may also be used to identify T lymphocytes, and have proven to be more sensitive and discriminatory (Table 2).[26-61] Many of these antibodies react with immature T cells; others react with more mature T cells. Some of these antibodies identify antigens found on all T cells, whereas others occur only on T cell subsets.

Myeloid cells. Monoclonal antibodies to cell suface markers on peripheral blood myeloid cells and their bone marrow progenitors have been extensively investigated.[62-125] Some of these monoclonal antibodies detect antigens expressed by either peripheral blood monocytes or neutrophils. Other reagents identify surface markers common to monocytes and neutrophils; monocytes, neutrophils, and large granular lymphoid cells (LGL); monocytes and platelets; or neutrophils and LGLs (Table 3).

The expression of several monoclonal antibody-defined myeloid antigens corresponds to pathways of normal differentiation within the myeloid lineage. These antibodies are

therefore useful as tools for identifying hematopoietic cells at various stages of maturation and proliferative potential (Table 4 and Fig 1). Using either complement-dependent monoclonal antibody-mediated lysis (negative selection), or techniques such as fluorescence-activated cell sorting or immune rosetting (positive selection), it is possible to determine patterns of antigen expression by multipotent stem cells (CFU-GEMM) and by stem cells committed to the myeloid (CFU-GM), erythroid (BFU-E, CFU-E), or megakaryocyte/platelet (CFU-Mega) pathways of differentiation. In several reports, myeloid progenitor cells have been purified 50- to 100-fold from bone marrow mononuclear cells[85,126] enabling studies of morphologic and functional characteristics. Certain determinants are uniquely expressed by progenitor cells (eg, MY-10); other antigens are detectable on myeloid, erythroid, or platelet precursors corresponding to morphologically and histochemically distinct stages of maturation within the bone marrow. In the case of neutrophil differentiation, some antigens are either lost (Ia, MY-10) or acquired (Mo1, MY8, 80H.3, or B34.3) as cells progress from myeloblasts to mature neutrophils. Expression of other determinants (82H5, R1B19, S4-7) are maintained on all recognizable myeloid cells.

Although many of these antigenic determinants operationally serve as differentiation markers, some represent epitopes on functionally significant plasma membrane proteins, glycoproteins, and glycolipids. The glycoprotein heterodimer identified by the murine monoclonal antibodies Mo1 and OKM1 is a receptor for the binding of particles opsonized with C3 cleavage product C3bi (CR3 activity).[127,128] Antibodies B73.1 and 3G8 identify an Fc receptor for IgG that is expressed by LGL and/or neutrophils.[93,112] Data from immu-

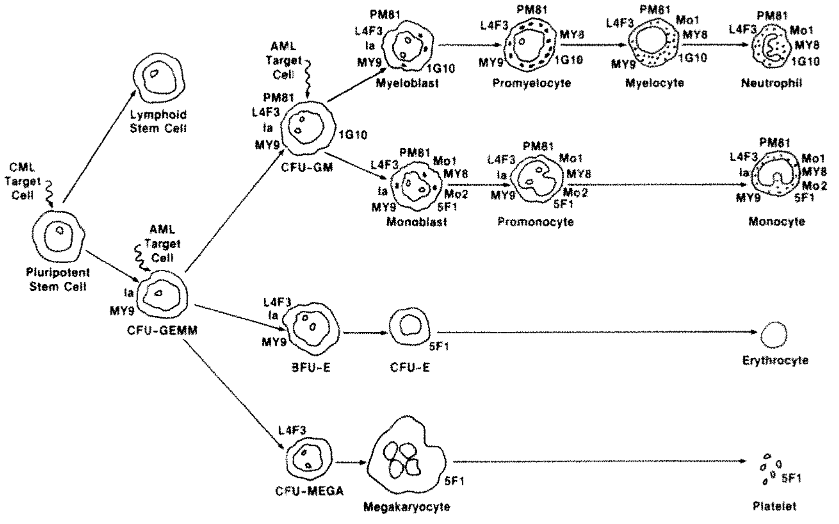

Fig 1. Schematic representation of human myeloid differentiation indicating the cell surface marker phenotype (as defined by selected well-characterized monoclonal reagents) of identifiable maturational steps. Phenotypic expression by monoblasts and promonocytes is tentative and based on positive expression by immature-appearing monocytoid cells in bone marrow. The phenotypes of CFU-GEMM, CFU-GM (early *or* late), BFU-E, CFU-E, and CFU-MEGA are based on the outcome of positive and/or negative selection (antibody-dependent, complement-mediated lysis, immunorosetting, or cell sorting) of human bone marrow cells on subsequent colony growth. Phenotypes of other cells are based on immunofluorescence analyses. Hypothesized sites of CML and AML leukemogenesis are indicated.

Table 5. Monoclonal Antibodies Leukemia-Associated Antigens

Antibody (Subclass)	Pattern of Reactivity	Molecular wt of Antigen (kd)	Cluster Designation	Reference
J5, BA-3, anti-CALLA	Most non-T-ALL, Burkitt's lymphoma, follicular lymphoma, some lymphoblastic lymphoma and T-ALL, rare normal cells	100	CD10	130-136
RFB-1	Myeloid progenitor cells, immature lymphoid bone marrow cells	NR	NA	141
BA-2, SJ-9A4 Du-ALL-1	Lymphohematopoietic bone marrow progenitor cells, most non-T-ALL, platelets	24	CD9	137-140, 142
Anti-3-3	T-ALL	35-40	NA	143
Anti-3-40	T-ALL, some non-T-ALL, rare AML vinentin and keratin intermediate filaments in normal cells	35-40	NA	143, 144
SN1	T-ALL	NR	NA	145
CALL2	T-ALL	NR	NA	146

NR, not reported; NA, not applicable.

J5 is available through Coulter Immunology, Hialeah, Fla; BA-2 and BA-3 through Hybritech Inc, San Diego.

noprecipitation or immunoblotting analyses indicate that several of these antibodies are specific for epitopes on the same parent structure or even the same epitope.

Leukemia-associated antigens. The common acute lymphoblastic leukemia-associated antigen (CALLA) was originally defined by antiserum produced in rabbits by immunization with SmIg-negative, sheep erythrocyte rosette–negative acute lymphoblastic leukemia (ALL) cells.[129] This antiserum reacted with a 100 kd glycoprotein antigen. Monoclonal antibodies that recognize CALLA (CD10) have recently been described (Table 5).[130,131] Although CALLA is absent on normal peripheral blood lymphocytes, it is not leukemia specific, and is present on normal terminal deoxynucleotidyl transferase (TdT) and Ia antigen–positive bone marrow cells that are thought to be lymphohematopoietic precursor cells.[132] CALLA has also been identified on renal tubular and glomerular cells, mammary epithelium, fetal small intestine epithelial cells,[133] granulocytes,[134] fibroblasts,[134] and melanoma cell lines.[135] CALLA is also present on Burkitt lymphoma cells, follicular lymphoma cells, and cells from 40% of patients with lymphoblastic lymphoma.[136]

P24/BA-2 is a second leukemia-associated antigen with a mol wt of 24 kd defined by the BA-2,[137] SJ-9A4,[138] and DU-ALL-1[139] monoclonal antibodies (CD9). These antibodies do not react with any normal circulating hematopoietic cells except for platelets. They react with most non-T ALL cells and, like CALLA, the P24/BA-2 antigen is present on ~3% to 9% of sheep erythrocyte receptor and SmIg negative TdT positive bone marrow mononuclear cells. This may also represent a bone marrow-derived lymphoid progenitor cell. The anti-J2 antibody[140] has a similar pattern of reactivity as do the BA-2, SJ-9A4, and DU-ALL-1 antibodies. The J2 antigen is also present on activated normal T lymphocytes and may react with the same surface molecule as BA-2. The RFB-1 antibody likewise reacts with immature lymphoid cells in the bone marrow,[141] but differs from BA-2 in its reactivity with myeloid progenitor cells.[141,142] The anti-3-3, anti-3-40,[143,144] SN1,[145] and CALL2[146] antibodies identify antigens found on T-ALL cells but not generally on non-T-ALL or other malignant or normal hematopoietic cells. A summary of the most frequently referenced antibodies and their cluster designations is presented in Table 6.

Immunoglobulin and T cell receptor genes. Recombinant DNA technology has provided important insights into antibody diversity and antigen-specific T cell receptors.[147,148] Immunoglobulins are composed of heavy and kappa and lambda light chains, encoded by genes on chromosomes 14, 2, or 22, respectively.[149-152] Immunoglobulin genes are encoded by discontinuous segments of DNA.[153-158] At one point in development, a potential antibody-producing cell must productively rearrange variable, diversity, and joining genes

Table 6. Frequently Referenced Antibodies with Cluster Designations

Cluster Designation	Antibody
CD1	OKT6, anti-Leu-6, NA1/34

(VDJ), which are then linked to the constant region locus. Immunoglobulin gene rearrangements are hierarchical; μ heavy chain rearrangements precede light chain rearrangements, and κ light chain rearrangement precedes λ light chain rearrangements.[156–158] These rearrangements can be detected by Southern blot analyses of DNA from B cells using appropriately radiolabeled heavy or light chain probes. Heavy chain rearrangements have been identified in non-B cells, but light chain rearrangements appear to be restricted to B cells.[157,159,160] Clonal rearrangements of light chain genes are therefore an extremely sensitive tool to identify B cell malignancies.

The antigen-specific T cell receptor is a heterodimer formed by a 40- to 50-kd α subunit ($T\alpha$), and a 40- to 45-kd β subunit ($T\beta$).[161] It is associated with three 20- to 25-kd peptide chains identified by the T3 monoclonal antibody.[161] Recently, cDNA clones to the $T\beta$ and $T\alpha$ receptors have been isolated.[162–166] The human $T\beta$ receptor gene has been localized to chromosome 7[167] and the human $T\alpha$ receptor gene maps to chromosome 14.[168] The less well-defined $T\gamma$ receptor gene is currently under investigation. The T cell receptor genes undergo rearrangements in a fashion analogous to that of immunoglobulin genes. The $T\gamma$ receptor gene has been shown to be rearranged in murine cytotoxic T lymphocyte cell lines but not myeloma cell lines.[169] Similar to the $T\beta$ chain gene, the $T\gamma$ gene rearrangement appears to occur early in T cell development, whereas $T\alpha$ chain expression occurs later in thymic ontogeny.[170]

T_β gene rearrangements have been detected in malignant human T cells by Southern blotting.[171–173] This technique can detect as few as 1% tumor cells in a mixed cell population[171]; it is a sensitive diagnostic marker for T cell diseases. Rearrangements of the $T\beta$ antigen receptor are reported in 25% of patients with non-T ALL,[174] and in a small proportion of patients with B cell leukemia.[175] This is similar to the rearrangement of immunoglobulin heavy chain genes in 10% of patients with T cell leukemia.[159,160]

Intracellular enzymes and biochemical markers. TdT is present in thymocytes and in a small percentage of bone marrow cells, but not in mature lymphocytes.[176,177] TdT is identified in all subtypes of ALL and is, therefore, not discriminative. TdT has also been demonstrated in a small proportion of acute myelogenous leukemia (AML) cells.[178] Other intracellular enzymes reported useful in identifying subsets of ALL include hexosaminidase, adenosine deaminase,[180] 5'-nucleotidase,[181] purine nucleoside phosphorylase,[182,183] and acid phosphatase.[184] Acid phosphatase is present in T-ALL cells but not in non-T-ALL cells. Cytochemical reactions are useful in the subclassification of AML.[185,186] The M1 through M3 myeloid subtypes contain myeloperoxidase and sometimes nonspecific esterase. Myelomonocytic leukemia cells (M4) also contain myeloperoxidase and nonspecific esterase; the latter is variably inhibited by sodium fluoride. Acute monocytic leukemia (M5) cells contain myeloperoxidase and nonspecific esterase which is completely inhibited by sodium fluoride.

Several surface membrane-associated biochemical markers of leukemia cells have also been described. The glycolipid asialo GM1 is found on cells from patients with ALL (non-T-ALL and T-ALL) but not on cells from patients with other forms of leukemia.[187] Alterations in membrane carbohydrates, such as decreased complex gangliosides,[188] carbohydrate-containing antigens,[189] and receptors for cholera toxin[190] have been reported on leukemia cells.

CLASSIFICATION OF THE LYMPHOID LEUKEMIAS AND LYMPHOMAS

Acute lymphoblastic leukemia. ALL is heterogeneous. The first surface markers used to differentiate subclasses of ALL were receptors for sheep erythrocytes,[191–193] which identify a T cell subset (15% to 20% of cases), and SmIg, which identifies a B cell subset (<5% of cases). Both T and B cell subgroups have an unfavorable prognosis.[194,195] The next important advance in identifying ALL was the development of an antiserum to CALLA.[129] CALLA reactivity identified a non-B, non-T subclass of ALL patients (~70% of cases) with a more favorable prognosis than T-ALL, B-ALL, or non-B, non-T-ALL without CALLA.[195] Other markers such as Ia antigen were commonly found on non-T-ALL and could help differentiate non-T-ALL from T-ALL.[196] By testing for $C\mu$ heavy chain, a subset designated pre-B ALL has been identified.[197–199] Except for the presence of $C\mu$, this subset expresses the same surface markers as the CALLA form of non-T-ALL; it appears, however, to have a less favorable prognosis.[200]

With the development of monoclonal antibodies, it became evident that the T cell subset of ALL was heterogeneous.[201–205] More recently, studies employing immunoglobulin gene rearrangements and monoclonal antibodies that identify B cell-associated antigens have demostrated that most cases of non-T-ALL are derived from the B cell lineage.[156,206–208] We review these data and present a new classification for ALL based on these recent observations.

Non-T-ALL. Two important areas of research have prompted a reassessment of non-T-ALL. First, monoclonal antibodies that recognize B cell-associated antigens have been identified; many are present on non-T-ALL cells. The most specific of these antibodies is probably anti-B4, which react with 95% of cases of non-T-ALL.[11,208] Second, clonal rearrangements of immunoglobulin genes provide strong evidence for the B cell lineage of most cases of non-T-ALL.[156,206,208]

Although Ia antigen is present on most non-T-ALL cells, and CALLA is present in 75% of cases of non-T-ALL, these antigens are also identified on ~10% of cases of T-ALL. Therefore, B cell-associated antigens (Table 1), which are not identified on T-ALL cells, are the most useful in distinguishing non-T-ALL. The B1 and B4 antigens are model antigens for this discussion.

Less than 5% of cases of ALL express SmIg (usually IgM); these cells are typically classified as B-ALL. These cells generally express other B cell antigens, including B1 (CD20), B4 (CD19), and Ia. B-ALL in children is probably a leukemic phase of non-Hodgkin's or Burkitt's lymphoma.[193,194] Another marker that identifies a subset of non-T-ALL is $C\mu$ heavy chain; κ and λ light chains and SmIg are typically absent.[197] These cells are considered pre-B cells. As indicated, most cases of non-T-ALL cells of B lineage; thus Cμ is useful in determining the level of differentiation. Pre-B cells that synthesize μ heavy chain are more mature than those pre-B cells that do not synthesize μ heavy chain, but are less mature than those with SmIg.

Nadler and co-workers[208] recently classified 138 patients with non-T-ALL. They divided these cases into four major subgroups. The first subgroup was Ia antigen positive, representing 5% of cases. Another subgroup expressed the Ia and B4 antigens, representing 15% of cases. The third subgroup expressed the Ia, B4, and CALLA antigens, comprising one third of the cases. Finally, one half of the cases of non-T-ALL were Ia, B4, CALLA, and B1 positive. The fourth group was further subdivided into cases with and without Cμ. We propose that cases with Cμ be placed in a separate group (group V). The final and most differentiated group, group VI, represents SmIg-positive B-ALL (Table 7).

Nadler and co-workers[208] also studied immunoglobulin gene rearrangements in cells from patients in groups II, III, and IV. Patients in group II (Ia and B4 positive) demonstrated rearranged heavy chain genes, with germ lines for both κ and λ light chain genes. Based on these data, they hypothesized that the group II phenotype represents the earliest stage in B cell maturation. Patients in group III had rearranged heavy chain genes and most had κ light chain gene recombination, either rearrangement or deletion. Patients in group IV had rearranged heavy chain genes; two of four had deletions of κ.

Virtually all non-T ALL cells have immunoglobulin heavy chain rearrangement; not all of them, however, demonstrate light chain rearrangements. Because heavy chain rearrangements also occur in non-B cells[159,160] immunoglobulin heavy chain rearrangements are insufficient to assign non-T-ALL to the B cell lineage. Nadler and co-workers have proposed that the B4 antigen provides the most important independent parameter with which to identify B cell-derived non-T cell ALL. More recently, up to 25% of non-T ALL have been reported to have rearrangements of the Tβ receptor.[174] This observation emphasizes the necessity of combining DNA genotyping and surface marker analyses for more precise classification of leukemia and lymphoma. The remaining 5% of morphologically and cytochemically defined non-T cell ALLs (group I), which express the Ia but not the B4 antigen, most likely represents the earliest stage of pre-B cell differentiation. This hypothetical scheme of early B cell differentiation is further supported by data demonstrating that all of the proposed ALL subgroups can be identified in normal fetal liver and bone marrow and in normal adult bone marrow.[208]

Table 7. Classification of Non-T-ALL

Group	Antigens				Cytoplasmic μ	Surface Membrane Immunoglobulin
	Ia	B4	CALLA	B1		
I	+	−	−	−	−	−
II	+	+	−	−	−	−
III	+	+	+	−	−	−
IV	+	+	+	+	−	−
V	+	+	+	+	+	−
VI	+	+	+/−	+	−	+

T-ALL. T-ALL represents 15% to 25% of cases of ALL. Clinical features associated with T-ALL include a high blast cell count, predominance of older male patients, and mediastinal masses. T-ALL was originally identified by rosetting with sheep erythrocytes. The most sensitive marker for T-ALL is probably the pan-T 40 kd antigen identified by the anti-Leu-9 antibody (CD7). This antigen is present on most thymocytes and T cells but not on non-T-ALL or B cell lymphomas or leukemias.[45-48] In a study of 23 patients with T-ALL, all cases expressed the Leu-9 antigen.[46] Although it was previously reported that anti-Leu-1 (CD5) is the most sensitive marker for T-ALL,[202,209] three of these 23 patients whose cells were anti-Leu-9 positive were negative with anti-Leu-1.[46] Anti-Leu-9 reacts with a small proportion of cases that appear to be myeloid leukemias.[210] In addition, an unusually high incidence of CALLA, Ia, and BA-2 expression has been reported in adults with T-ALL.[211] Recently, rearrangement of the Tβ receptor gene in cases of T-ALL has been reported.[171-175] Two cases of T-ALL with the phenotype of early thymocytes were reported to have no rearranged Tβ receptor genes, suggesting that Tβ rearrangement may occur later in thymocyte development.[212]

Further subclassification of T-ALL is controversial. Reinherz and colleagues proposed a subclassification for T-ALL according to the level of thymic differentiation.[201] Several elements of their subclassification of T-ALL have been confirmed; others are controversial. The most primitive thymocytes, referred to as early or stage I thymocytes, react with T9 and T10 antibodies and account for ~10% of the thymic cells. In their study, Reinherz and co-workers reported that most T-ALL cells express antigens found on early thymocytes. The next level of thymic differentiation, which includes the majority of thymocytes, is referred to as common or stage II. These cells lose T9, retain T10, and acquire T6 (CD1), T4/Leu-3 (CD4), and T8/Leu-2 (CD8) antigens. Approximately 20% of cases of T-ALL express this phenotype. Mature stage III thymocytes no longer express T6 but segregate into T4/Leu-3 or T8/Leu-2 subsets similar to peripheral blood T lymphocytes. Only rarely did Reinherz and colleagues find T-ALL cells with the phenotype of mature thymocytes or circulating T lymphocytes. In a more recent study, Roper and coworkers[204] confirmed many of the findings reported by Reinherz and colleagues, but reported some major differences. In this study, only one third of the T-ALL patients had the phenotype of early or stage I thymocytes; most had the phenotype of either intermediate or late stage thymocytes.

In Table 8, we summarize these data and propose a scheme for the classification of T-ALL. The common marker for all of the subgroups is Leu-9. Nearly all cells also express Leu-1 and most express T11/Leu-5 (CD2) that identifies the receptor for sheep erythrocytes. Cells in subgroup I also express T9 and/or T10. The pan T antigen, identified by T3/Leu-4 (CD3), represents a mature antigen and is not found on group I cells. The T4/Leu-3 helper-associated antigen, the T8/Leu-2 suppressor-associated antigen, and the T6 antigen are not expressed on group I cells.

The next level of differentiation is group II. T9 is found on some cells;[204] however, the T6 antigen as well as the simulta-

Table 8. Classification of T-ALL

	Antigens						
Group	Leu-9*	Leu-1	T11/Leu-5	T3/Leu-4	T4/Leu-3	T8/Leu-2	T6
I	+	+ (90%)	+ (75%)	−	−	−	−
II	+	+	+	+ (25%)	+ (90%)	+ (90%)	+
III	+	+	+	+	+/−†	+/−†	−

*Found on virtually all T-ALL cells.

†No longer simultaneous expression of T4/Leu-3 and T8/Leu-2 as found in group II.

neous expression of T4/Leu-3 and T8/Leu-2 antigens clearly distinguish group II from group I. Some cells in group II may also express T3/Leu-4. Group III T-ALL cells lose the T6 antigen and segregate into cells that have the phenotype of mature thymocytes and T lymphocytes (T3/Leu-4, T4/Leu-3 or T3/Leu-4, T8/Leu-2).

Although Roper and co-workers[204] searched for clinical correlations among these three groups of T-ALL, they found no unique clinical features among the subgroups and no differences in remission duration or survival. However, the groups were too small for statistically valid conclusions. Presently, we believe it useful to subclassify T-ALL using this system, so that data from a number of institutions can be analyzed for clinical correlations between the subgroups of T-ALL (Table 8).

Non-Hodgkin's lymphoma. The non-Hodgkin's lymphomas are a diverse group of neoplasms whose pathologic classification is controversial. It is even more difficult to correlate pathologic classification with immunologic classification. Several immunologic patterns emerge, however, and we will attempt to place them within the non-Hodgkin's lymphoma working classification[213] as well as the Rappaport classification.[214,215]

Follicular or nodular lymphomas. The follicular or nodular lymphomas most likely represent neoplastic proliferation of lymph node-derived follicular center B lymphocytes. The cell type may be a small cleaved cell (nodular lymphocytic poorly differentiated lymphoma by the Rappaport classification), mixed small cleaved and large cleaved or noncleaved cells (nodular mixed), or predominantly large cell (nodular histiocytic). The first two cell types fall within the working classification as low-grade lymphoma, whereas the latter cell type is classified as an intermediate-grade lymphoma. Although the predominantly small cleaved cell will almost always express high-density monoclonal SmIg, larger cells may be SmIg negative.[216,217] However, the small cleaved and large cells will routinely express Ia, B4, and B1 antigens and will often express the B2 antigen.[217] More than half of these cases will also express CALLA.[217,218] Follicular lymphoma cells may be found in the peripheral blood as a "leukemic" phase of the disease (formerly referred to as lymphosarcoma cell leukemia). These cells can usually be differentiated from chronic lymphocytic leukemia (CLL) cells because they may express CALLA, which is not expressed on CLL cells; they do not express the T1/Leu-1 pan-T antigen found on CLL cells; and they generally will have a low percentage of mouse erythrocyte rosette formation (see below).[219,220]

Malignant lymphoma, small lymphocytic. Malignant lymphoma, small lymphocytic (diffuse lymphocytic well-differentiated lymphoma in the Rappaport classification) is a low-grade malignancy, and some cases may be identical to CLL. Also included within this subclassification are the plasmacytoid lymphocytic subgroups with and without an IgM monoclonal gammopathy; some of these cases are similar to Waldenström's macroglobulinemia (described below). Surface markers on these small lymphocytic cells include low-intensity SmIg, mouse erythrocyte receptors, C'3 and receptors for the Fc portion of IgG, and Ia, B1, B2, B4, BA1, and other B cell antigens. These features are similar to CLL, and the cells also express the T1/Leu-1 pan-T antigen.

Malignant lymphoma, diffuse small cleaved cell and diffuse mixed small and large cell. Malignant lymphoma, diffuse small cleaved cell (diffuse lymphocytic poorly differentiated lymphoma in the Rappaport classification) is an intermediate prognostic group. The cells are B lymphocytes that (similar to follicular lymphoma cells) usually display large amounts of monoclonal SmIg. Unlike follicular lymphoma cells, however, they do not usually express CALLA.[218] Similar to follicular lymphoma cells, they do not express the T1/Leu-1 antigen as do cells from most small lymphocytic lymphomas and CLL. However, all these cell types have in common the expression of Ia, B4, B1, B2, and other B cell antigens.[217]

The diffuse mixed small and large cell (diffuse mixed lymphocytic-histiocytic) lymphomas have not been extensively studied but are most likely predominantly B cell diseases. They are also considered an intermediate-grade prognostic group.

Malignant lymphoma, diffuse large cell and large cell immunoblastic. In the working classification, the diffuse large cell lymphomas are considered within the intermediate prognostic group, whereas large cell immunoblastic lymphoma is a high-grade malignancy. By the Rappaport classification, both of these cell types would be described as histiocytic. This is clearly a misdesignation since 80% to 90% of cases represent clonal expansions of malignant B cells.[217,221] A high percentage of these cells express T9 and T10 antigens.[216] Fifty-seven cases of diffuse large cell lymphoma were recently studied and divided into the following subgroups: (a) B1, B4, and SmIg positive; B2 negative (50%); (b) B1, B4, SmIg, and B2 positive (30%); (c) B1 and B4 positive; SmIg and B2 negative (10%); and (4) B1 and SmIg positive, and B2 negative (10%).[222] These data suggest that most of these lymphomas represent the malignant counterpart of B cells at the midstage of differentiation. Ten to 20 percent of cases are T cell lineage; 2% are derived from the monocyte-myeloid lineage. Recently, clonal rearrangement of the Tβ receptor has been described in patients with T-derived non-Hodgkin's lymphoma.[172,173]

Malignant lymphoma, lymphoblastic. Malignant lymphoma, lymphoblastic, or lymphoblastic lymphoma, is a high-grade malignancy. The nuclear membrane is characteristically deeply subdivided, exhibiting either a lobulated (convoluted) appearance or a fine linear (nonconvoluted) subdivision in a round nucleus. Lymphoblastic lymphoma represents approximately one-third of the cases of non-Hodgkin's lymphomas in children and 5% of cases in adults. The disease is more prevalent in males; these patients often have a mediastinal mass. In some cases, the disease may evolve into a leukemic phase morphologically indistinguishable from T-ALL. The malignant cells are T cells, form E rosettes, react with T cell antisera,[223-225] and have rearrangements of the Tβ receptor.[226] Studies with monoclonal antibodies have demonstrated marked heterogeneity. Lymphoblastic lymphoma cells differ from T-ALL in that the cells rarely express the surface markers common to immature thymocytes (group I);[227] phenotypes are equally divided between group II and group III T-ALL. In 40% of cases, the cells are reported to express CALLA; CALLA expression is less common in T-ALL (10%).[218]

Malignant lymphoma, small noncleaved cell. Malignant lymphoma, small noncleaved cell includes Burkitt's lymphoma and other lymphomas previously designated undifferentiated non-Burkitt type (high grade). Burkitt cells from peripheral blood and bone marrow are usually classified as L3 by the FAB criteria.[185,186] Most cases of Burkitt's lymphoma from Africa are endemic and are associated with the Epstein-Barr virus (EBV). Most non-African cases (nonendemic) are EBV negative.[228] Chromosomal abnormalities involving chromosome 8 (carrying the oncogene c-*myc*) and either 2, 14, or 22 occur in virtually all cases of endemic and nonendemic Burkitt's lymphoma.[229] These are designated t(2;8), t(8;14) and t(8;22), respectively. Usually the light chain class expressed on these cells is correlated with the translocation, ie, κ in t(2;8) and λ in t(8;22). African Burkitt's lymphoma cells have receptors for C'3 and for the Fc portion of IgG in addition to the EBV receptor. American Burkitt's lymphoma cells do not express these receptors.[228] Phenotyping of cell lines derived from patients with undifferentiated lymphoma of the Burkitt's and non-Burkitt's type have demonstrated heterogeneity.[230] These studies suggest that Burkitt cells follow a divergent pathway of B cell evolution because they are all TdT negative (unlike early B cell non-T-ALL). The most primitive of the Burkitt cell lines are Ia and B1 positive and may or may not express CALLA. Maturation was evident in other Burkitt cell lines by the expression of Cμ, surface membrane IgM, and/or IgM secretion. Some of these Burkitt cell lines also expressed the Tac antigen.

Peripheral T cell lymphoma. Peripheral T cell lymphoma would usually be classified as malignant lymphoma, large cell immunoblastic (high grade) under the working formulation. However, this tumor has unique features and will be described separately. The term "peripheral T cell lymphoma" is used to distinguish it from lymphoblastic lymphoma of presumed thymic origin. Peripheral T cell lymphomas are thought to derive from peripheral T lymphocytes in lymph nodes and other nonlymphoid sites. These lymphomas comprise a broad spectrum of morphologic types of lymphocytes. In all instances, the cells have T cell markers admixed with epithelioid histiocytes, plasma cells, eosinophils, and vascular hypertrophy. Clinically, peripheral T cell lymphoma is characterized by generalized lymphadenopathy, weight loss, and a high incidence of pulmonary involvement.[231] Surface markers are usually but not always characteristic of mature T helper cells,[232] including the T4/Leu-3 helper-associated antigen and the T3/Leu-4, T11/Leu-5, and T1/Leu-1 pan-T antigens. Rearrangement of the Tβ receptor has been reported.[226]

Tγ lymphoproliferative disease. Tγ lymphocytes are a subset of T lymphocytes with receptors for the Fc portion of IgG. A high proportion of normal Tγ lymphocytes are LGL. These cells are thought to be responsible for natural killer (NK) and antibody-dependent cell-mediated cytotoxicity in humans[233] and rodents.[234] A lymphoproliferative disorder made up of predominantly Tγ lymphocytes has been described; we refer to this as chronic Tγ lymphoproliferative disease.[235] Typically, patients are elderly males with increased Tγ lymphocytes infiltrating the bone marrow and spleen.[235,236] Although the disease is not rapidly progressive, neutropenia and recurrent infections are common. Most patients do not require chemotherapy. Variants of this disease, including a more aggressive form, have been described.[237] Clonal chromosomal abnormalities,[238] as well as clonal rearrangement of the Tβ receptor, have been reported.[175,239] Cells from chronic Tγ lymphoproliferative disease usually contain acid phosphatase and β-glucuronidase and express the pan-T antigens T3/Leu-4, T11/Leu-5, the suppressor-associated antigens T8/Leu-2, and the NK-associated antigen Leu-7 (HNK-1). Other monoclonal antibodies that react with LGL[240,241] may also prove to be useful.

Cutaneous T cell lymphoma (mycosis fungoides, Sézary cell leukemia). Skin lesions are the most prominent feature of patients with cutaneous T cell lymphoma.[242] Lesions vary from limited plaques to diffuse generalized plaques, tumors, and generalized erythroderma. Rare patients with limited plaque disease and <50% with generalized plaques and tumors have extracutaneous disease detected by light microscopy evaluation of peripheral blood and lymph nodes. Special studies including cytogenetic analysis and electron microscopy indicate blood involvement in >50% of patients with limited plaque disease and most patients with generalized plaques and skin tumors.[243] Analysis of the Tβ receptor rearrangement will likely reveal a higher proportion of cases with nonmalignant cells in the blood and lymph nodes.

The malignant cells in this disorder are characterized by a cerebriform nucleus. In the skin, the cells are referred to as mycosis fungoides cells and in the peripheral blood as Sézary cells. Sézary and mycosis cells form E rosettes, react with T antisera and anti-T monoclonal antibodies,[244,245] and have clonal rearrangements of the Tβ receptor.[173,175,226,246] In most cases, the cells express the phenotype associated with normal helper/inducer T lymphocytes (T-1/Leu-1, T3/Leu-4, T4/Leu-3 positive)[247-251] and function as helper T lymphocytes in in vitro assays.[252] The 3A1 antibody (CD7), which reacts with >85% of normal circulating T lymphocytes and with mycosis cells in the skin, does not generally react with Sézary cells in the blood.[253]

Adult T cell leukemia/lymphoma. Adult T cell leukemia/lymphoma is associated with a human retrovirus designated human T cell leukemia/lymphoma virus-1 (HTLV-1).[254,255] Virtually all patients tested have antibodies to HTLV-1.[256] Patients with this disease have been identified primarily in Japan, the United States, and the Caribbean. In the United States, the patients are young (median age 33 years), predominantly black, and born in the southeast.[253] Common clinical features include a rapid onset of symptoms with rapidly progressive cutaneous lesions and hypercalcemia. Skin lesions are variable and include small and large discrete or confluent nodules, or nonspecific plaques, papules, or patches. Patients have increased bony turnover with abnormal bone scans and elevated alkaline phosphatase and may have lytic bone lesions.[257] Lymphocytosis is common, and circulating malignant cells are present in low numbers in most patients. Peripheral lymphadenopathy is common, with retroperitoneal and hilar involvement in approximately 50% of cases. Bone marrow, gastrointestinal, pulmonary, leptomeningeal, and hepatic involvement are somewhat less common (20% to 50%). Response to combination chemotherapy is prompt and often complete, but duration of response is short (median 13 months). Opportunistic infections are extremely common in these patients.

The typical malignant circulating cells have moderately condensed nuclear chromatin, inconspicuous nucleoli, and a markedly irregular nuclear contour in which the nucleus is divided into several lobes.[258] These cells typically express the phenotype of helper/inducer T lymphocytes,[259-261] and the Tac antigen (CD25) that identifies the IL-2 receptor.[262] Variability in the expression of T3, T11, and T12 have been reported.[261] Clonal rearrangements of the Tβ receptor are identified in cells from patients with adult T cell leukemia/lymphoma.[173,175,226,239] The leukemic cells are reported to suppress B cell Ig secretion[263] by a complex mechanism involving induction of suppressor cells following activation of normal suppressor cell precursors.[261]

CLL and prolymphocytic leukemia. CLL is a monoclonal proliferation of SmIg-positive B lymphocytes.[264,265] Clonality of CLL has been demonstrated by expression of a single Ig light chain, either κ or λ, on the cell surface membrane.[266,267] More sophisticated techniques have confirmed clonality by showing unique immunoglobulin idiotype specificities,[268] a single pattern of glucose-6-phosphate dehydrogenase activity,[269,270] clonal chromosome abnormalities,[271] or immunoglobulin gene rearrangement.[157] The malignant B cell involved in CLL is an intermediately differentiated cell. The cell appears frozen in differentiation and does not mature to the final stage of B cell development, the mature plasma cell. However, recent data have demonstrated that in vitro treatment of these cells with phorbol esters or pokeweed mitogen can induce differentiation into mature immunoglobulin-secreting plasma cells.[272] In another study, this immunoglobulin secretion was preceded by a rapid increase in the level of mRNA coding for IgM, a predominantly secretory form of mRNA rather than a membrane form of mRNA.[273] This selection is similar to that seen in plasma cells, and the study clearly demonstrated at the molecular level that CLL cells consistently retain the capacity to differentiate to plasma cells and secrete immunoglobulin. Under certain circumstances, CLL cells stimulated in vitro with phorbol esters differentiate into cells with cytoplasmic protrusions and other characteristics of hairy cell leukemia.[274]

The B lymphocyte characteristic of CLL displays a relatively small amount of SmIg, estimated to be ~9,000 molecules per cell.[275] Relatively weak fluorescence of SmIg has been used to distinguish CLL from the leukemic phase of nodular and diffuse lymphocytic lymphomas and from prolymphocytic leukemia in which the cells generally display considerably more SmIg.[276,277] Immunoglobulin isotype analyses indicate that most CLL display a single heavy chain class; typically, μ or μ and δ. Less commonly, γ, α, or no heavy chain determinant is found. CLL cells display either κ or λ light chains but never both. Some data suggest that heavy chain switching can occur in B-CLL, which may indicate increasing maturity of the malignant cell.[277] Other studies indicate that CLL cells contain only μ or μ and δ and that γ is extrinsic and not synthesized by the leukemic cells.[278] Although there has been controversy as to whether CLL B cells contain CIg, the presence of cytoplasmic heavy chains (μ and δ) has been reported in most patients with CLL; no γ or α chains were detected.[279] B-CLL cells display receptors for mouse erythrocytes, a feature characteristic of immature B lymphocytes.[280] The cells also have the receptor for the Fc portion of IgG and complement with a relative increase of C'3d receptors (CR2) over C'3b receptors (CR1); this is typical of immature B cells.[281] B-CLL cells display several antigens, including Ia and human B cell antigens such as BA1, B1, B2, and B4. One unanticipated finding was that B-CLL cells display a 65-kd glycoprotein antigen previously thought to be restricted to T lymphocytes. This antigen was first recognized by using heteroantisera[282]; later, it was recognized with the T101 and equivalent monoclonal antibodies.[31-33] The precise meaning of this anomalous expression of a T cell antigen is unclear, although a normal B cell counterpart has been reported in human tonsil lymph nodes,[283] and stimulation in vitro of normal B cells with phorbol ester may induce expression of this antigen.[284] Recently, the TQ1 antigen, reported to define the inducer of suppression within the T helper subset, was identified on 60 of 75 B-CLL patients' cells.[285]

Rearrangement of immunoglobulin heavy and light chains has been reported as expected in B-CLL cells; however, rearrangement of the Tβ receptor has also been reported in ~10% of cases of B-CLL.[175] This is analogous to the reported Tβ rearrangement in 25% of non-T (pre-B) ALL, and again emphasizes that immunoglobulin and Tβ receptor rearrangement alone are not adequate to assign lineage.

In 3% to 10% of patients with CLL, the disease may evolve into a diffuse histiocytic lymphoma (Richter's syndrome). This is associated with loss of the TQ1 antigen.[285] Most data suggest that this evolution involves transformed follicular center B cells rather than histiocytes or macrophages. Some transformations represent evolution of the malignant clone with expression of the same monoclonal immunoglobulin and karyotypic abnormality present in the original CLL clone.[286] In other cases, the lymphoma cells have different markers and immunoglobulin gene rearrangements than those of the original CLL cells; these cases probably represent the concomitant development of a B cell lymphoma or a histiocytic malignancy in patients with CLL.[287,288]

Prolymphocytic leukemia (PL) is related to CLL and is also likely to be derived from cells from the medullary cords of the lymph node. Immunoglobulin gene rearrangements of heavy and light chains have been reported.[289] Patients with PL generally have extremely high blast counts and splenomegaly but lack significant lymphadenopathy. Prolymphoblasts likely are activated cells and appear morphologically immature, with a fine lacy nuclear chromatin and one to two nucleoli; they may contain intracytoplasmic granules. These cells generally have higher density SmIg than do CLL cells; they have Ia and B4 antigens and may form rosettes with mouse erythrocytes.[220] PL cells from 14 consecutive patients reacted with the FMC7 monoclonal antibody that recognizes an antigen found on one half of normal B lymphocytes, whereas cells from only 5 of 20 patients with CLL reacted with this antibody.[7]

Approximately 5% of cases of CLL and PL result in a malignant proliferation of T rather than B cells. These cells react with T antisera and anti-T monoclonal antibodies reflecting the phenotypes of mature T lymphocytes; they lack SmIg and other B cell markers.[290,291] Many of these patients have diffuse organ and skin involvement.[290] T-CLL cells have been reported to have either helper or suppressor surface markers.[202,292,293] One patient's cells rosetted with sheep erythrocytes expressed the Leu-2 (suppressor-associated) antigen and also had SmIg and CIg (IgMλ).[294] Other instances in which the leukemia/lymphoma cells expressed characteristic features of both B and T lymphocytes have also been reported.[295]

Hairy cell leukemia. Hairy cell leukemia (leukemic reticuloendotheliosis) is characterized by invasion of the bone marrow and spleen by morphologically distinct mononuclear cells with "hairy" cytoplasmic projections.[296] These cells usually contain an isoenzyme of acid phosphatase (isoenzyme 5) that is resistant to tartrate; this isoenzyme is not unique to hairy cells. Surface markers of hairy cells are most consistent with a monoclonal proliferation of B lymphocytes.[297-300] SmIg with a single light chain is frequently identified,[299,300] as are B cell-associated antigens including Ia, B1, FMC-1, FMC-7, and sometimes BA-1.[299-301] The PCA-1 antigen (but not the PC-1 antigen) typically on plasma cells is identified on hairy cells; these data suggest that hairy cells may be pre-plasma cells.[302] Perhaps the most convincing evidence for the B cell origin of hairy cells comes from studies of immunoglobulin genes which indicate clonal rearrangement of heavy chain genes and at least one light chain gene.[303,304] Most cases of hairy cell leukemia demonstrate the 53-kd to 57-kd Tac antigen (IL-2 receptor) typically identified on select T cell malignancies and activated T cells.[304] Another antigen with a mol wt of 52 to 67 kd, designated HC-2, appears to be restricted to hairy cell leukemia cells.[305,306] The αS-HCL 1 antibody reacts with normal B lymphocytes and B cell malignancies, including hairy cell leukemia.[109] The αS-HCL 3 reacts with normal monocytes and AML cells but is restricted to hairy cell leukemia among the lymphoid malignancies.[109] Approximately 2% to 3% of normal peripheral blood B lymphocytes express this antigen; these appear to be activated B cells.

Myeloma and related disorders. The malignant B cells of Waldenström's macroglobulinemia, heavy chain disease, and multiple myeloma represent a further step in the maturation of medullary cord B cells.[264] Like CLL cells, cells from patients with Waldenström's macroglobulinemia express SmIg and Ia, B1, and B4 antigens.[11] Unlike CLL cells, however, these cells express the PCA-1 antigen but do not express the B2 antigen nor do they rosette with mouse erythrocytes.[4,220] The plasma cell and its malignant counterpart, the myeloma cell, represent the most differentiated B lymphocytes. These cells synthesize large quantities of immunoglobulin and have CIg, but usually lack SmIg and the Ia, B1, B2, and B4 antigens.[307] Plasma cells and myeloma cells, like other mature B lymphocytes, usually lack CALLA, but a recent study has suggested that rare cases of CALLA-positive myeloma represent an aggressive subtype with a poor prognosis.[308] Plasma cells and myeloma cells stain intensely with the OKT10 monoclonal antibody as well as the anti-PCA-1 and anti-PC-1 antibodies.[309,310]

CORRELATES OF CELLULAR DIFFERENTIATION WITH LYMPHOID MALIGNANCIES

Substantial data suggest that the phenotypes of most leukemia cells are not unique but reflect characteristics of normal cells. None of the surface markers we have reviewed are leukemia specific; all can be identified on normal as well as malignant cells. Most of the monocyte, granulocyte, and lymphocyte antigens are found on mature and immature cells. However, CALLA, BA-2, and RFB-1 are expressed primarily on immature bone marrow cells. This observation is consistent with the phenotypes of leukemic cells, since the CALLA and BA-2 antigens are present on primitive leukemia cells (ALL and lymphoid blast crisis of chronic myelogenous leukemia cells) but only rarely on more mature leukemia or lymphoma cells. Distribution of the reactivity of the monoclonal T antibodies is likewise consistent with this hypothesis. The most primitive thymocyte markers, OKT9 and OKT10, are found on most T-ALL cells, whereas T3/Leu-4, T8/Leu-2, and T4/Leu-3, which are found on mature thymocytes and circulating T lymphocytes, are more often identified on more mature T cell leukemias.

A proposed scheme of normal lymphoid differentiation is presented in Fig 2. This scheme is based on the concept that the phenotype of normal lymphoid cells at each level of differentiation can be detected from the phenotype of its malignant counterpart. Although some malignant cells may have an aberrant phenotype, the data presented suggest that

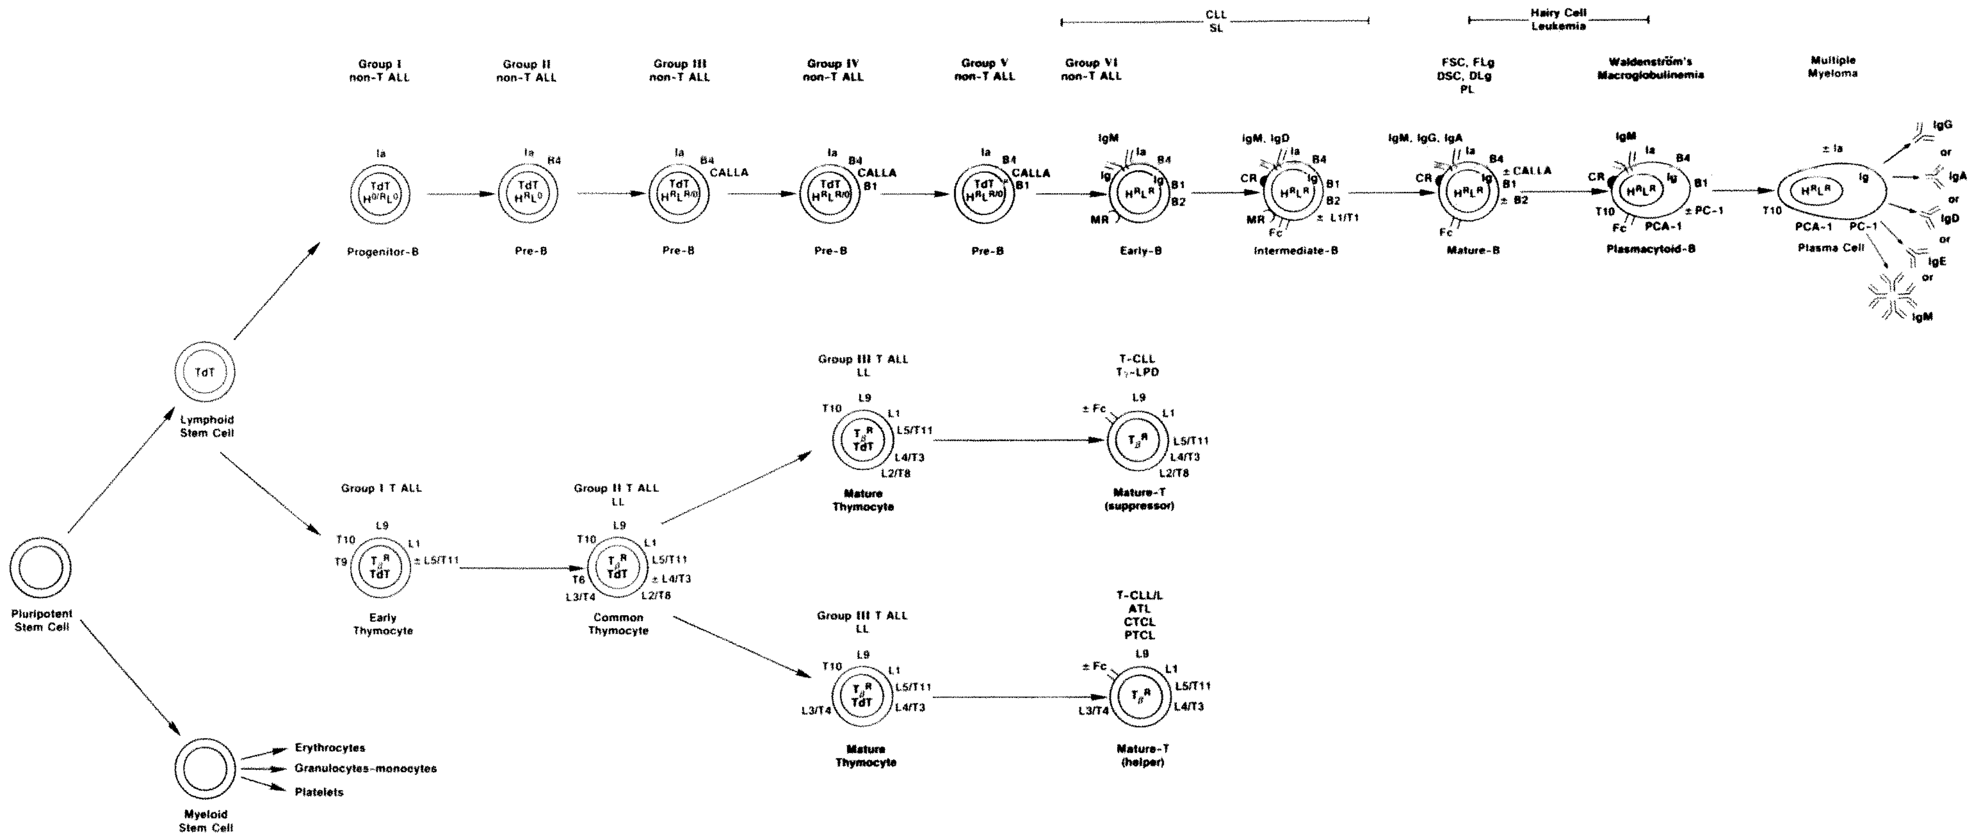

Fig 2. Schematic representation of human lymphoid differentiation and related lymphoid malignancies. ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; SL, malignant lymphoma, small lymphocytic; FSC, malignant lymphoma, follicular small cleaved cell; FLg, malignant lymphoma, follicular large cell; DSC, malignant lymphoma, diffuse small cleaved cell; DLg, malignant lymphoma, diffuse large cell; PL, prolymphocytic leukemia; LL, lymphoblastic lymphoma; Tγ-LPD, Tγ-lymphoproliferative disease; ATL, adult T cell leukemia/lymphoma; CTCL, cutaneous T cell lymphoma; PTCL, peripheral T cell lymphoma; TdT, terminal deoxynucleotidyl transferase; H, heavy chain; L, light chain; O, germline configuration; R, rearranged gene; T_β^R, clonal rearrangement of the Tβ receptor; MR, mouse rosette; CR, complement receptor.

most malignant lymphoid cells reflect the phenotype of a normal lymphocyte. The proposed phenotype of the progenitor B lymphocyte probably has the same surface markers as the group I non-T-ALL and represents the earliest identifiable B cell. This cell expresses the Ia antigen, but no other B cell-associated antigens. The next level of B cell differentiation coincides with the group II non-T-ALL; heavy but not light chain immunoglobulin genes are rearranged. At the next level of B cell differentiation, the cells express CALLA and light chain gene rearrangements occur; this coincides with group III non-T-ALL. With sequential steps in B cell differentiation, the B1 antigen is expressed, followed by Cμ and then SmIg. At the next level of B cell differentiation, the B cell acquires the B2 antigen and the receptor for mouse erythrocytes; both SmIg and CIg are present. Most CLL cells—and malignant lymphoma, small lymphocytic type cells—express the phenotype of intermediate B lymphocytes. The cells express receptors for complement and the Fc portion of IgG, Leu-1, in addition to the surface markers identified on more primitive B cells. At this level of differentiation, there is low-density SmIg. The maturing B cells express high-density SmIg (IgM, IgG, or IgA) without B2 or mouse erythrocyte receptors. The malignant counterparts of the mature B cell are the follicular small cleaved and large cell lymphomas and the diffuse small cleaved and large cell lymphomas and PL cells. At the next step of maturation, the plasmacytoid B cell secretes Ig, usually of the IgM subclass, and expresses new surface membrane antigens including OKT10, PCA-1, and PC-1. It has recently been demonstrated that hairy cell leukemia falls somewhere between the mature B cell and plasma B cell; they also express the PCA-1 antigen.[302] The plasma cell, the most differentiated B lymphocyte, expresses the same phenotype as myeloma cells. Although these cells have CIg, produce immunoglobulin, and express OKT10, PC-1, and PCA-1, they lose other surface membrane markers, including SmIg, Ia, and B cell antigens.

T cell differentiation follows a distinct pathway. Early thymocytes (stage I) express Leu-9, Leu-1, T9, T10, and often T11/Leu-5 (sheep erythrocyte receptor); this phenotype probably represents the malignant counterpart of group I T-ALL cells. A case has been made that the stage I thymocyte has not yet rearranged the Tβ receptor gene[212]; this remains to be confirmed. The common thymocyte (stage II) no longer expresses T9; it gains T6 antigen and simultaneously expresses the helper-associated (T4/Leu-3) and suppressor-associated antigens (T8/Leu-2). This cell clearly rearranges the Tβ gene, confirming that Tβ rearrangement precedes surface membrane expression of the T3–Ti complex.[212] This cell corresponds to the phenotype of group II T-ALL and some lymphoblastic lymphomas. Subsequently, the cells lose either the helper-associated or suppressor-associated antigens. This is equivalent to group III T-ALL or some cases of lymphoblastic lymphoma. In the final stage of maturation, the suppressor-associated cell (T8/Leu-2) may express the receptor for the Fc portion of IgG as well as the surface markers previously attributed to the mature thymocyte (including the T3–Ti complex), coinciding with the phenotype of some T-CLL cells and chronic Tγ lymphoproliferative disease. The helper-associated mature T lymphocyte (T4/Leu-3), on the other hand, may express the receptor for the Fc portion of IgM and coincides with the phenotypes of some T-CLL, adult T cell leukemia/lymphoma, cutaneous T cell lymphoma, and peripheral T cell lymphoma.

CLASSIFICATION OF THE NONLYMPHOID LEUKEMIAS AND LYMPHOMAS

Hodgkin's disease. Hodgkin's disease (HD) is a malignant neoplasm of uncertain cellular origin characterized by the appearance of distinctive binucleate or multinucleate giant cells (Reed-Sternberg cells, RSCs) and their mononuclear variants (Hodgkin's cells, HCs).[311] The malignant nature of this disease is suggested by cytogenetic studies that have shown a clonal distribution of chromosomal aneuploidy.[312–314] Considerable debate has arisen as to what constitutes the malignant cell of HD. However, most investigators now agree that the RSCs or HCs (a subset constituting a minute fraction of the tumor mass) represent the neoplastic cell population.[315] The normal cellular counterpart from which RSCs and HCs arise has not yet been identified.[315]

Investigators have used morphology (light and electron microscopy), cell culture, and immunohistochemistry in an attempt to characterize the nature of the RSCs and HCs. Based on these observations, it has been argued that HD arises from the T lymphoid,[316,317] B lymphoid,[318–328] or myeloid-macrophage lineages.[311,329–331] Although this controversy is unresolved, the application of immunologic marker analysis has contributed to our further understanding of the disease, and several general statements can be made. First, with few exceptions, most observers have failed to detect the uniform expression of T cell surface markers (as defined by polyclonal and monoclonal reagents)[328,332–337] by RSCs or HCs, suggesting that these cells are not of T lymphocyte origin. RSCs and HCs have been shown to express the Tac antigen (IL-2 receptor)[338]; in two reports, these cells were found to be T9 positive (transferrin receptor).[332,334] Neither receptor-associated marker is restricted to the T cell lineage.[304,339] Second, although the detection of SmIg or CIg in RSCs and HCs favors a B cell origin,[318,319,322] the expression of these determinants is often polyclonal,[321,340–344] which suggests that immunoglobulin is adsorbed onto RSC and HC cells rather than being synthesized by the malignant cell.[340] There are no convincing data that RSCs or HCs produce immunoglobulin. Immunologic staining of RSCs and HCs for the expression of B cell differentiation antigens has produced conflicting results.[332,333,345] In an interesting case of B cell HD,[346] a patient with nodular sclerosing HD developed a terminal leukemic phase. The circulating HCs expressed the B1 and B4 antigens and had cytoplasmic μ heavy chains and a clonal rearrangement of heavy and light chains (consistent with a B cell origin). Substantial data, however, favor a myeloid-macrophage origin for HD.[340,341,344,347–349] This conclusion is based on the demonstration of nonspecific esterase (NSE) and acid phosphatase, α-1-antitrypsin and α-1-antichymotrypsin, muramidase, lectin-binding properties, and the variable expression of Fc and C3 receptors on

RSC and HC cells. Although short-term cell lines believed to be derived from RSCs demonstrate weak phagocytic activity, and one line was reported to synthesize IL-1,[347,349] other established cell lines have not uniformly shown these activities.[350] In most instances, RSCs and HCs do not react with antibodies to monocytes,[318,332–336,345,350] although in one report a substantial number of biopsy specimens contained RSC and HC positive for markers characteristic of late granulocytic maturation (TU5, TU6, TU9).[333,351] Based on Ia expression[318,332,336,345] and characteristic cytochemical features, other authors have suggested that the cell of origin for HD is a "reticulum cell" (either a dendritic cell or an interdigitating reticulum cell).[336,352] Finally, some data suggest that the RSCs and HCs represent a subset of activated lymphoid cells of either T or B lymphoid origin. This conclusion is based on an immunologic analysis in which RSC and HC uniformly expressed the Ki-1 marker (35 of 35 biopsy specimens of all histological subtypes) as defined by a monoclonal antibody raised by immunization against an established HD cell line.[353] Among normal cells, Ki-1 is expressed by T and B lymphocytes activated in vitro by various stimuli that also induce interleukin-2 (IL-2) receptor expression.[337] In situ staining of biopsy specimens from nonneoplastic and reactive tissues demonstrated Ki-1 expression by a population of normal perifollicular lymphoid cells (lymph node and spleen) and variable degrees of expression by abnormal lymphoid cells in cases of angioimmunoblastic lymphadenopathy and lymphatoid papulosis. Among 290 cases of non-Hodgkin's lymphoma, Ki-1 expression was observed in 19 cases of peripheral T cell lymphoma and in 45 cases of diffuse large cell lymphoma (including 35 specimens expressing T cell surface markers and 7 bearing B cell antigens). These results suggest that Ki-1 is a lymphoid activation antigen that identifies a group of large lymphoid cells in normal and neoplastic tissues (including RSCs) that remains poorly characterized. Another monoclonal reagent, HeFi-1, is similar if not identical to Ki-1.[354]

In summary, the cellular origin for HD remains unclear. Although Ia and T9 antigen staining of RSC and HC cells have been reported, Ki-1 antigen expression may prove to be the most useful immunologic marker for this disease.

RSCs and HCs constitute only a small portion of cells within the tissue of Hodgkin's disease. Recent efforts are directed toward characterizing the remaining cells and have been recently reviewed.[355] Use of in situ techniques has demonstrated that lymphoid tissues involved with HD appear to be heterogeneous in immunohistologic make-up; some cases demonstrate numerous T lymphocytes with few B cells, whereas others exhibit prominent follicles of polyclonal B lymphocytes and only small numbers of T cells within these follicles. In two studies,[335,355] these B cell-rich cases were of the lymphocyte-predominant type. In specimens containing T lymphocytes, RSCs and HCs tend to appear in areas of heaviest T cell infiltration, suggesting a relationship. Many cells within areas of T cell infiltration are Ia or T10 positive, suggesting that these T lymphocytes are activated. Several investigators have demonstrated that most HD-associated T lymphocytes are of the helper cell subset.[332,335,355–357] Genotyping for immunoglobulin and T cell receptor rearrangements may lead to a better understanding of the cellular origin of this disease.

Malignant disorders of macrophages. Several malignant diseases of macrophages (or histiocytes) have been described.[358,359] The term histiocytic lymphoma, used in the Rappaport classification,[215] encompasses a heterogeneous group of neoplasms of large transformed lymphocytes and, rarely, of macrophages.[360,361]

The malignancies of macrophages (histiocytosis X) are heterogeneous.[362] Clinical presentations include solitary benign eosinophilic granuloma, Hand-Schuller-Christian disease, and histiocytic medullary reticulosis; the latter is a generalized systemic disorder characterized by fever, wasting, hepatosplenomegaly, variable lymphadenopathy, and progressive pancytopena due to diffuse tissue invasion by malignant macrophages.[363] The equivalent disease in children is sometimes referred to as Letterer-Siwe disease. Because of morphologic and ultrastructural similarities between malignant macrophages and epidermal Langerhans cells, it has been proposed that these diseases represent a proliferative disorder of Langerhans cells.[364–366] Both cell types possess receptors for C3 and the Fc portion of IgG[367] and express the T6 and Ia antigens.[368,369] The malignant macrophages also express the OKM1 and other macrophage surface markers.[370] An unexpected and unexplained finding was the presence of the T4 antigen in this disorder.[368]

AML. AML is a clonal malignancy of myeloid progenitor cells resulting in excessive proliferation and accumulation of immature hematopoietic elements. The subtypes of this disease are generally classified according to the morphologic similarity of the leukemic cell population to normal myeloid precursors, eg, acute myeloblastic leukemia, acute promyelocytic leukemia, acute monoblastic leukemia, and acute erythrocytic leukemia.

Monoclonal antibodies have been evaluated for reactivity against AML cells (Tables 9 and 10). In all cases, these antibodies identify determinants expressed by either normal circulating myeloid cells or bone marrow progenitors. None of these reagents recognizes a leukemia-specific determinant and, with few possible exceptions,[371–373] attempts to generate leukemia-specific antisera have been unsuccessful. Studies of the reactivity of antimyeloid cell antibodies for AML cells have raised several issues: (a) whether these reagents are specific in their reactivity for myeloid *v* lymphoid leukemia cells; (b) whether antibody reactivity correlates with classification using the FAB nomenclature; (c) whether surface marker expression by myeloid leukemia cells corresponds to stages of normal myeloid differentiation and, if so, whether this is of prognostic significance; (d) whether myeloid leukemia cells in a patient are homogeneous in their expression of surface markers; (e) whether leukemia progenitor cells defined by their ability to form leukemic colonies in vitro exhibit the same antigenic phenotype as their progeny in bone marrow and blood; and (f) whether monoclonal antibodies that identify antigens expressed by myeloid leukemia cells can be used for immunotherapy.

AML v the lymphoid leukemias. Because of differences in prognosis and therapy, it is important to distinguish between AML and the lymphoid leukemias. Although differ-

ences in morphology and histochemistry often lead to the correct diagnosis, the distinction between immature variants of AML and ALL is not always evident. Monoclonal reagents that identify antigens expressed by myeloid but not lymphoid leukemias (or vice versa) would therefore be important. Six monoclonal antibodies have been extensively tested for reactivity to myeloid and lymphoid leukemia (Table 9). Each of the six antigenic determinants defined by these antibodies (Mo1/OKM1, MY7, MY8, MY9, VIM-2, and VIM-D5) is expressed by more than one half of patients with AML (53% to 91%), defined as antibody binding by >10% to 20% of malignant cells in each patient. The myeloblasts of patients with myeloid blast crisis of CML demonstrate similar frequencies of expression for these determinants except for MY8. Conversely, expression of these antigens on acute lymphoid leukemia cells (including the T and B cell variants of ALL and chronic myelogenous leukemia (CML) lymphoid blast crisis) is rare. Clearly, these monoclonal reagents can complement other tests in the differential diagnosis of AML versus ALL. The accuracy of immunologic diagnosis can be extended by using more than one antimyeloid reagent in conjunction with antibodies that detect antigenic determinants uniquely expressed by B or T lymphoid leukemias (anti-CALLA, B1, B4, OKT3, Leu-4, etc.) (see above). Occasionally, however, this approach has produced seemingly disparate results, with the detection of leukemia cells with myeloid and lymphoid differentiation markers.[374–376] These rare situations may reflect the existence of biopotential clones of malignant cells expressing features of more than one lineage.[377]

Correlation between surface marker phenotype and FAB classification. There are several types of AML differ in morphology, histochemistry, and surface marker expression. Classifications have been proposed to identify these types, based on the hypothesis that this information may be of prognostic and therapeutic significance. The FAB group classification, which relates the morphologic appearance of leukemic cells to presumed normal hematopoietic counterparts, is widely used.[185,186,378,379] Seven subtypes of AML (M1 through M7) are identified: M1 and M2 represent undiffer-

entiated and differentiated myeloblastic leukemia; M3, promyelocytic leukemia; M4 and M5, myelomonocytic and monocytic variants; M6, erythroleukemia; and M7, megakaryocytic leukemia. Although some investigators have reported briefer remissions or lower response and survival rates in patients with the M5 variant,[380-382] fewer remissions in erythroleukemia (M6),[380] or longer remissions in promyelocytic leukemia (M3),[380-382] these observations are controversial.[186,381-383] With the development of immunologic reagents that detect antigenic markers expressed by normal and leukemic myeloid cells, analyses have been undertaken to compare the FAB system with patterns of surface marker expression. Table 10 indicates 16 monoclonal reagents whose relative reactivity against FAB-classified AML variants can be critically assessed. Within the first group of seven antibodies (VIM-2, R1B19, S4-7, PM81, MY9, MY7, and Mo5), no clear distinction exists in antigen expression by cells in each of the five FAB variants (M1-M5; too few patients with the M6 and M7 variants were examined to draw conclusions). The frequency of expression by patients in each subclass is generally 50%. In the second group of seven antibodies (MOP9, AML-2-23, MY4, UCHM1, MY8, Mo1/OKM1, and Mo2), there is a trend toward higher frequency of antigen expression among individuals whose leukemia cells display monocytic differentiation (M4 + M5). In the case of VIM-D5 and 82H5, only undifferentiated M1 cells have a lower frequency of expression. None of these reagents demonstrates preferential binding frequency to M1 and/or M2. One antibody, VIE-64, which binds to glycophorin A, displays relative binding specificity toward M6 variant cells.[384] Monoclonal antibody SFL 23.6 has a well-defined reactivity restricted to the erythroid lineage including erythroleukemia cell lines and should be useful in distinguishing M6.[125] Monoclonal antibodies against platelet glycoproteins Ib, IIb/IIIa, and aIIIaa, for factor VIII-related antigen can be used to identify megakaryoblasts.[378] With these possible exceptions, the degree of correlation between surface marker expression and the criteria for FAB classification is not convincing.[385,386]

Subclassification of AML according to differentiation-associated phenotypes as identified by monoclonal antibodies. Because there is controversy over whether the FAB classification system provides prognostic information, alternative classifications have been proposed. In a surface marker analysis of 70 patients with AML, Griffin and co-workers[119] identified four phenotypes based on patterns of surface antigen expression that correlated with phenotypes displayed by myeloid cells during normal differentiation. Group I AML cells (21% of patients) expressed the antigenic phenotype of the CFU-C–committed myeloid progenitor cell (Ia and MY7-positive); group II cells (26%) displayed the phenotypic characteristic of normal myeloblasts (MY7, Ia, and Mo1/OKM1 and My8-positive); group III cells (8%) had a phenotype featured by normal promyelocytes (MY7 and Mo1/MY8-positive; Ia-negative); and group IV cells (45%) with the phenotype of promonocytes and monocytes (MY4, MY7, MY8/Mo1, and Ia-positive). Within these four differentiation-related groups there was considerable morphologic heterogeneity: although all three of the promyelocytic leukemia (M3) patients were in group III and all six monocytic leukemia (M5) patients were in group IV, the myeloid leukemia (M1 and M2) and myelomonocytic leukemia (M4) patients were dispersed throughout all four groups, with a tendency for myeloid patients to be in groups I, II, and III, and myelomonocytic patients to be in groups II and IV. The preliminary finding of a larger prospective analysis involving over 200 patients demonstrates significant differences among these phenotypic groups with respect to complete response rate and disease-free survival (J.D. Griffin, personal communication). Moreover, expression of certain markers appears to be of independent prognostic significance: AML patients with MY7-positive leukemia exhibit a worse prognosis than do MY7-negative patients; the expression of monocyte antigen MY4 is also predictive of a poor response. Several studies of the biological implications of surface marker phenotype in AML are in progress.

A scheme for myeloid differentiation is shown in Fig 1. In an attempt to account for the FAB M4 leukemic cell (bearing features of both granulocytic and monocytic differentiation), Ball and Fanger[122] have proposed that the normal M4 counterpart is an intermediate bipotential precursor cell capable of differentiating along either the monocytic or granulocytic path of differentiation. They further suggest that the myeloblast (M1 and M2), the progenitor of the M4 cell, is likewise bipotential. Given the ability of the promyelocytic leukemia cell line HL-60 to undergo subsequent differentiation toward mature monocytes or neutrophils depending on the nature of the inducing stimulus,[387,388] it appears that the normal promyelocyte is not irreversibly committed to granulocytic maturation. Although these hypotheses are consistent with some experimental observations, considerable additional data are required.

Heterogeneity of surface marker expression by malignant AML cells. Most studies of AML indicate considerable heterogeneity in leukemic cell surface marker expression between patients as well as within a given individual.[62,67,69,95,114,118,122,386,389] Typically, a patient is classified as positive for the expression of a marker if >10% to 20% of the patient's leukemia cells display the determinant. Although certain antigens tend to be expressed by >50% of the leukemic cells of given individuals, variability is considerable. If surface marker expression correlates with the level of myeloid differentiation, these data suggest that the leukemic population is heterogeneous.

AML likely arises from leukemic myeloid progenitor cells, which in some cases can be grown in vitro in semisolid medium.[390-392] The clonogenic leukemia cells (L-CFC) are, by definition, capable of limited proliferation (with a subset capable of self-renewal), a feature that distinguishes them from most leukemia cells that are terminally differentiated.[392,393] Several groups have recently investigated the surface marker characteristics of L-CFC and compared them with the total leukemia population.[70,114,394,395] The surface-marker phenotype of the total leukemia population, as determined by immunofluorescence analysis, may not predict the phenotype of the L-CFC as measured by inhibition of L-CFC growth after antibody-dependent, complement-mediated lysis. In general, the L-CFC has a pattern of antigenic expression that is more "immature" than that of the predominant phenotype of the total population. L-CFC have been subclassified using multiple markers whose expression on normal CFU-GEMM (Ia, MY9, S3-13, S8-6), early (day 14) CFU-GM (Ia, MY9, PM-81, S3-13, S8-6, S4-7), and late (day 7) CFU-GM (all of the preceding markers plus AML-2-23 and R1B19) are known. Three phenotypically distinguishable levels of differentiation have been identified.[114,394] The degree of maturity, as based on morphology (FAB classification) and expression of "later stage" antigens (beyond the CFU-GM: Mo1, MY3, Mo2) of the total leukemia population, tends to correlate with the L-CFC maturation level (eg, CFU-GEMM level L-CFC are associated with M1 morphology and lack expression of late antigens), suggesting a limited potential for terminal differentiation[114,395] These data suggest that L-CFC are a distinct subset of clonogenic cells among the total leukemia population; these cells may arise at multiple points along the pathway of early myeloid differentiation.

CML. CML is a myeloproliferative disorder characterized by a consistent chromosomal abnormality, the Philadelphia (Ph^1) chromosome. The Ph^1 chromosome results from a reciprocal translocation between chromosomes 9 and 22 designated t(9;22).[396] This translocation results in the transfer of the c-*abl* oncogene from chromosome 9 to the Ph^1 chromosome and the variable reciprocal translocation of c-*sis* from chromosome 22 to 9.[397] The target for leukemic transformation (Fig 3) appears to be at the level of the pluripotential stem cell, since the Ph^1 chromosome is present in all hematopoietic elements of patients with CML, including B and T cells. [398-404] The clonal origin of CML is further indicated by analysis of patterns of expression of glucose-6-phosphate dehydrogenase (G6PD), and adenylate kinase isoenzyme.[398,402] In the chronic phase of the disease, CML is characterized by an overproduction of relatively mature granulocytes. After a variable period of time, with a median of 3 years, most patients enter an acute phase (blast crisis) in which maturation no longer occurs. The acute phase resembles acute leukemia. Approximately one-third of patients with acute-phase CML demonstrate cells with lymphoid features that include the expression of TdT, CALLA, Ia, B1, rarely $C\mu$ and rearrangements in immunoglobulin heavy and light chain genes.[403,405-411] Rare cases of lymphoid acute phase with T cell markers have also been reported.[412-414] Acute phase CML involving myeloid cells is heterogeneous; typically the cells resemble myeloblasts, but erythroblasts, megakaryoblasts, and monoblasts can also be observed. Distinction between lymphoid and myeloid acute phase is important because patients with lymphoid blast crisis may respond to chemotherapy with vincristine (V) and prednisone (P).[410,415-417] In making this diagnostic distinction, the characteristic expression of several myeloid markers (MY7, MY9, VIM-2, and Mo1/OKM1) on myeloid blast crisis cells and their lack of expression by lymphoid blast crisis cells (Table 9) provide information complementary to assays for the detection of CALLA, B1, TdT, and CIg.[38,66,70,105,106,118,119,124,409,418,419]

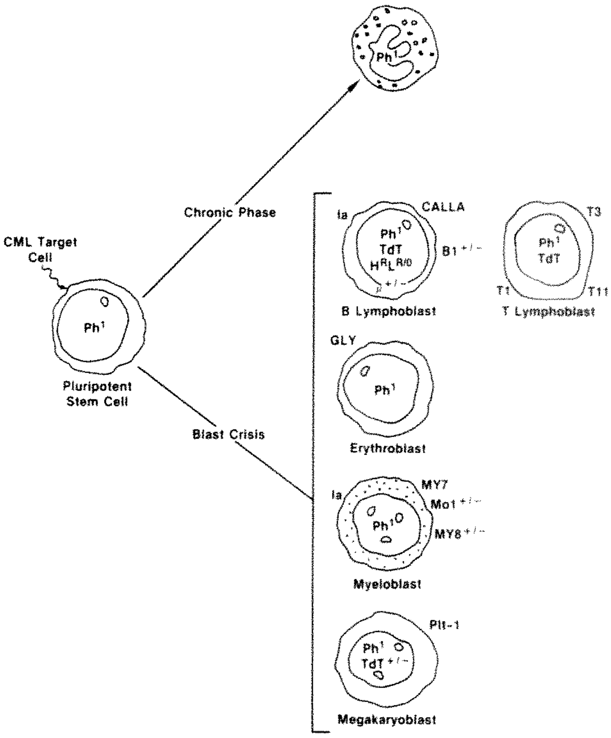

Fig 3. Schematic representation of the origin of chronic and blast crisis phase of chronic myelogenous leukemia (CML) from the target pluripotent stem cell. Phenotypes for various forms of CML blast crisis (based on data of Griffin et al[419]) are indicated. Ph^1, Philadelphia chromosome; TdT, terminal deoxynucleotidyl transferase; GLY, glycophorin A.

Surface marker analysis may allow further discrimination among the heterogeneous presentation of CML acute phase. Four phenotypes were identified in 30 patients with this disorder based on antigen expression of normal myeloid, erythroid, megakaryocytic, and lymphoid cells.[419] The cells of ten patients exhibited a phenotype corresponding to an immature myeloid cell (Ia, MY7, and Mo1-positive); all ten were negative for CALLA, B1, and TdT. These cases were felt to represent "myeloid" blast crisis; none of these patients responded to treatment with V and P. Cells from 11 patients expressed a phenotype similar to acute (early B) lymphoblastic leukemia cells (TdT, Ia, CALLA, and B1-positive; MY7 and Mo1-negative); six of nine evaluable patients had a complete response to V and P. Cells from one patient had the phenotype of erythroleukemia (glycophorin A-positive); another patient's cells expressed the phenotype of megakaryocytic leukemia (Plt-1-positive); one patient's cells had features of both myeloid and lymphoid blasts on different cells. Cells from six patients did not express surface markers characteristic of any lineage; these were termed "undifferentiated"; these cases were heterogeneous in expression of TdT; no complete responses to V and P were observed. Thus, in terms of response to V and P therapy, surface marker analysis provided useful prognostic information.

In another series of 45 patients with CML in blast crisis, 28 patients were classified as having "myeloid" blast crisis on the basis of reactivity with at least one of six antimyeloid monoclonal reagents (including VIM-D5 and VIM-2) and no surface expression of T or B cell immune markers or

TdT.[420] Among these myeloid cases, however, only 11 patients expressed granulomonocytic antigens exclusively; the blast cells of 17 patients were additionally positive for platelet/megakaryocyte markers (16 cases) and/or erythroid determinants (three cases). Whether the *same* blast cell co-expressed myeloid, megakaryocytic, or erythroid antigens was not determined. Fourteen patients were classified as having "lymphoid" blast crisis with the phenotypic pattern of CALLA-positive ALL (10 cases), pre-B cell ALL (three cases), or "Null" ALL (one case). Two patients demonstrated a mixed myeloid and lymphoid blast cell phenotype, and a single patient was unclassifiable. Sixteeen of these 45 patients were tested serially during the course of their illness and three demonstrated phenotypic changes. The immunological diagnosis of lymphoid blast crisis was associated with a higher rate of remission than was myeloid blast crisis (57% *v* 4%, respectively) and a longer median survival.

Certain patients with the Ph^1-chromosome are first diagnosed in the acute phase without a preceding history of a chronic phase.[415] Either a chronic phase never existed or it was never detected. Surface-marker analysis may be as useful in the subclassification of these patients' cells as it is in the more typical acute phase that is preceded by a chronic phase.

MONOCLONAL ANTIBODY THERAPY

Several investigators[421–431] have attempted to treat lymphoid or myeloid leukemias with monoclonal antibodies. In some studies, patients with advanced B cell-derived CLL received T101 monoclonal antibody.[421,422] T101 could be safely infused and led to transient reductions in circulating leukemia cells; there was, however, no sustained effect on the bone marrow, involved lymph nodes, or other organs. This therapy resulted in some intravascular cell injury, but destruction in the spleen, liver, and lungs was probably more important. Similar results have been reported in patients with adult T cell leukemia/lymphoma, ALL, and AML treated with other monoclonal antibodies.[423–425] Patients with cutaneous T cell lymphoma who received T101 or anti-Leu-1 have had only transient improvement in skin lesions and lymphadenopathy.[426–429] Side effects of monoclonal antibody therapy are usually minor. Respiratory distress following the rapid infusion of monoclonal antibody has been described,[422] and some patients have demonstrated transient elevation of serum creatinine and hepatic enzymes.[423]

Monoclonal antibody therapy has several shortcomings that must be addressed. First, treatment with antibodies such as T101 results in modulation of the antigen from the cell surface, which prevents antibody binding to the tumor cells. The T101 antigen-antibody complex is pinocytosed into the cytoplasm,[430] a phenomenon that might be advantageous when drugs or toxins are linked to the antibody to enhance its cytotoxicity. Antigen in the circulation poses another potential problem because it might prevent the antibody from reaching the tumor cells. Furthermore, murine antibodies can stimulate production of human anti-mouse antibodies which lead to antibody neutralization. This situation may be correctable by treatment with high initial doses of antibody ($>$ 500 mg) or by simultaneous treatment with immunosuppressive drugs to induce tolerance. In addition, the heterogeneity of antigen expression of tumor cells may necessitate therapy with more than one antibody. Clearly, monoclonal antibody therapy for leukemia and lymphoma is in its earliest stages.

An interesting therapeutic approach with monoclonal antibodies involves the use of anti-idiotype monoclonal antibody reactive with the idiotype of the immunoglobulin on malignant B cells. Such an antibody is by definition specific for a patient's tumor cells. A patient with B cell lymphoma in an accelerated phase who was unresponsive to conventional therapies was treated with an IgG_{2b} anti-idiotype monoclonal antibody.[431] Following eight intravenous (i.v.) infusions, the patient entered a complete remission that has been sustained for $>$3 years. Results were less impressive in other lymphoma patients treated with this approach with ~50% achieving short-lived partial remissions.[432,433] We developed several monoclonal anti-idiotype antibodies to cells from patients with leukemia and lymphoma.[268] The first patient to undergo treatment had advanced CLL. Sequential anti-idiotype monoclonal antibody therapy with IgG_{2b} and IgG_1 antibody provided no benefit. His therapy was limited because of circulating idiotype immunoglobulin that blocked the binding of the anti-idiotype antibody to the leukemia cells. We were able to reduce the circulating idiotype sufficiently with extensive plasmapheresis.

Although anti-idiotype antibody therapy remains an interesting area of investigation, its applicability is limited by patient specificity (ie, antibodies are "tailor-made" for a single patient) and the presence of antibody in the serum of many patients. Recent data indicate that some tumors are biclonal; this would require the use of more than one antibody.[434,435] In addition, the tumor cell idiotype may be unstable due to somatic mutation within the immunoglobulin variable region genes.[436,437]

A number of centers are studying toxin and drug conjugates with murine antibodies directed toward human tumors; clinical trials have just begun. Antisera and monoclonal antibodies conjugated to radionuclides for tumor imaging have been extensively studied; this subject was recently reviewed.[438] We have used the T101 antibody conjugated to ^{111}indium for imaging in 12 patients with cutaneous T cell lymphoma.[439,440] Tumors as small as 0.5 cm have been localized; however, nonspecific uptake of the immunoconjugate in the liver and spleen has prevented critical evaluation of these organs. This difficulty has been partially circumvented by the administration of intracutaneous injections of the immunoconjugate which cause it to be carried via the lymphatics directly to lymph node sites of disease.[441] This procedure does not, of course, facilitate visualization of extralymphatic disease.

Survival for patients with ALL following relapse has not improved over the past several years with chemotherapy drugs. Allogeneic bone marrow transplantation clearly leads to improved survival, but only 30% to 40% of patients have matched donors.[442–444] An alternative method to allogeneic bone marrow transplantation would make use of monoclonal antibodies to cleanse autologous bone marrow prior to bone marrow transplantation. Patients who are in clinical remission are likely to have morphologically undetectable tumor cells in their bone marrow; these cells may be identified and destroyed in vitro by specific antibodies and complement or antibodies conjugated to toxins. In one recently reported study, patients with ALL in second or subsequent remission had their bone marrow treated with a mixture of the BA-1, BA-2, and BA-3 monoclonal antibodies and rabbit complement.[445] All the patients were prepared for transplantation with cyclophosphamide and fractionated total body irradiation. Engraftment occurred in all the patients and 7 of the 23 patients were relapse-free from 6 to 32 months (median 21 months) posttransplantation. All but one of the deaths was caused by recurrent leukemia. The researchers concluded that autologous bone marrow transplantation using in vitro-treated marrow was safe, allowed engraftment, and resulted in prolonged survival in some patients with ALL in second or subsequent remission. Similar results have been reported for ALL patients treated with the J5 monoclonal antibody and complement.[446] Relapse of leukemia in these patients may result from the inadequacy of the preparative regimen used to treat the patients prior to transplantation, inadequate removal by the in vitro treatment with monoclonal antibody and complement, or possibly to the lack of the putative graft *v* leukemia effect described in allogeneic bone marrow transplantation.[447] Even in allogeneic transplantation, in which the preparative regimens are identical to those of autologous transplantation, >50% of the ALL patients relapse, suggesting that an insufficient preparative regimen may be the factor leading to relapse in autologous transplantation as well.

In another study, patients with advanced B cell non-Hodgkin's lymphoma underwent in vitro bone marrow treatment with the anti-B1 antibody and complement.[448] Ten of 17 patients are disease-free at a median follow-up of 22 months (L.M. Nadler, personal communication). Despite the presence of the B1 antigen on mature B cells, B cells recovered within the first few months after transplantation, suggesting that the normal B cell progenitor does not express the B1 antigen.

Another approach to cleansing bone marrow in vitro is the use of monoclonal antibodies conjugated to toxins. In one study, whole ricin was conjugated to the T101 and 3A1 antibodies.[449] It was demonstrated that 95% of the tumor colonies were killed whereas 96% of bone marrow progenitor cells survived. Similar results were reported for a panel of anti-T cell monoclonal antibodies conjugated to intact ricin.[450] Other investigators reported results of an immunotoxin synthesized with pokeweed antiviral protein and the B43 antibody directed against Burkitt lymphoma cells.[451] Immunotoxins may prove to have advantages over antibody and complement; not all antibodies fix complement, and immunotoxins may have greater cytotoxic capability.

The use of monoclonal antibodies and antibody immunoconjugates in the treatment and radioimaging of cancer is in its infancy. Although much work must still be done to address the problems of monoclonal antibody therapies, studies in animal tumor models and humans have clearly demonstrated that antibodies alone or antibody conjugates can be safely administered with minimal adverse effects; in selected cases, these may have diagnostic and therapeutic value. Nonspecific localization of antibody in the reticuloendothelial system, host antibody response, and antigenic heterogeneity are major obstacles to safe and effective treatment with monoclonal antibodies. These issues are under investigation in animal models and humans. Although anti-idiotype antibodies are highly specific and have produced excellent responses in a small number of patients, problems such as biclonality of some lymphomas, instability of the idiotype, and the difficulty of tailoring antibodies to individual patients clearly limit the role of anti-idiotype therapy. The utility of purging bone marrow in vitro with antibodies and complement (or antibodies coupled to toxins) is limited to only a few diseases. However, studies have demonstrated that tumor cells can be removed from the bone marrow following in vitro treatment with antibody and complement; treated bone marrow can successfully engraft, and a number of patients have remained disease-free for >2 years. Whether this is related to the in vitro treatment is unknown. This treatment may prove to be an important application of monoclonal antibody therapy, and it bypasses most of the problems associated with in vivo monoclonal antibody serotherapy. Perhaps the most important future role for monoclonal antibody therapy will be in patients with minimal disease in the "adjuvant" setting, in whom antibody conjugates may eliminate micrometastatic deposits of tumor cells. This remains to be addressed in controlled trials.

CONCLUSION

The application of hybridoma technology and the exciting discoveries in molecular biology over the past 10 years have led to major advances in our understanding of the cellular origin of leukemia and lymphoma and will likely lead to a better understanding of the etiology of these diseases. Utilizing these techniques, it is now possible to more accurately diagnose and classify these disorders, sometimes guiding therapeutic decisions. It is also possible to use molecular probes to detect minimal residual disease. In the future, monoclonal antibodies conjugated to isotopes, drugs, and/or toxins will likely have a role in the therapy of certain leukemias and lymphomas. We look forward to this exciting new era in cancer therapy and diagnosis.

ACKNOWLEDGMENT

The authors are grateful to Dr Robert Peter Gale for his critical review of this manuscript, and to Jerrie CeBulky for her skills, patience, and tenacity in typing this manuscript.

Dye-Mediated Photolysis of Human Neuroblastoma Cells: Implications for Autologous Bone Marrow Transplantation

By Fritz Sieber, Sanjay Rao, Scott D. Rowley, and Maya Sieber-Blum

Cells from three different human neuroblastoma cell lines and normal human bone marrow cells were exposed to the lipophilic fluorescent dye, merocyanine 540 (MC 540), and white light. In vitro clonogenic tumor cells were inactivated up to 25,000 times more rapidly than multipotent hematopoietic progenitor cells (CFU-GEMM). It is conceivable that this pronounced difference in sensitivity to MC 540-mediated photolysis can be exploited for the selective killing of residual neuroblastoma cells in autologous remission marrow grafts.

© 1986 by Grune & Stratton, Inc.

BONE MARROW transplantation allows escalation of antineoplastic therapy without regard to marrow toxicity. It thus affords a greater chance of eradicating tumors.[1,2] Autotransplantation of the patient's own cryopreserved remission marrow virtually eliminates one of the most serious complications of allogeneic marrow transplantation, graft-*v*-host disease (GVHD). It also obviates the need for HLA-identical allogeneic marrow donors.[3-7] However, if the tumor originated in or metastasized to the bone marrow, transplantation of autologous remission marrow carries a significant risk of reinfusing occult tumor cells.[8,9]

For many tumors, the minimal concentration of neoplastic cells required for their unequivocal detection in bone marrow is ~1%. Thus, in the worst situation, a clinical marrow graft could contain between 10^8 and 10^9 residual tumor cells and still be classified as a remission marrow graft. Much effort is therefore currently directed at developing more sensitive methods for the detection of residual tumor cells and methods for their selective elimination from autologous remission marrow grafts.[10-17]

Studies with experimental tumors have shown that most physical, pharmacologic, and immunologic purging procedures are capable of reducing the concentration of tumor cells by one to four (occasionally six) orders of magnitude. We may thus have to resort to combination purging protocols to process marrow grafts with high concentrations of residual tumor cells. A combination of methods that are based on different principles may be the most promising strategy.

We have recently shown that Neuro 2a and NB41A3 murine neuroblastoma cells are killed very rapidly when they are exposed to the lipophilic photosensitizer, merocyanine 540 (MC 540) and a strong source of white light.[17] By contrast, normal murine pluripotent hematopoietic stem cells are only minimally damaged by the same treatment. Lethally irradiated mice that are transplanted with photosensitized mixtures of tumor cells and normal marrow cells survive and remain free of disease.[17] In this article, we present evidence that the same approach may also be applicable to the purging of human marrow grafts contaminated with neuroblastoma cells. MC 540-mediated photolysis reduced the concentration of in vitro clonogenic human neuroblastoma cells 1,000-fold to 50,000-fold, yet preserved 55% of multipotent hematopoietic progenitor cells (CFU-GEMM) from normal bone marrow.

MATERIALS AND METHODS

Cells. The human neuroblastoma cell lines IMR-32 (CCL 127), SK-N-MC (HTB 10), and SK-N-SH (HTB 11) were obtained from the American Type Culture Collection (Rockville, Md) and maintained in a culture medium consisting of 10% heat-inactivated fetal bovine serum (FBS) (KC Biological, Lenexa, Kan) and 90% α-modified minimal essential medium (α-MEM) (α-medium; KC Biological). Aliquots from a frozen stock of cells were thawed at regular intervals to prevent the unintentional selection of mutants. All three lines were free of mycoplasma infections.

The IMR-32 line originates from an abdominal mass in a 13-month-old child with a tumor diagnosed as neuroblastoma with rare areas of organoid differentiation.[18] The line expresses adrenergic traits and consists of two morphologically distinct cell types, small neuroblast-like cells and large hyaline fibroblasts. The SK-N-MC line was isolated from a metastasis to the supraorbital area in a 14-year-old child.[19] The cells have epithelial-like morphology and express cholinergic traits. Surface marker patterns are consistent with those of a neuroepithelioma.[20] The SK-N-SH line was isolated from a bone marrow metastasis in a 4-year-old child.[19] The cells are epithelial-like with adrenergic characteristics. The IMR-32 line was established before treatment was initiated. The two other lines were established after the patients had received radiotherapy and chemotherapy.

Normal human bone marrow cells were obtained from healthy donors for clinical bone marrow transplants after informed consent had been obtained under a protocol approved by the Joint Committee on Human Investigation and in accord with an assurance filed with and approved by the Department of Health and Human Services. A mononuclear cell fraction was prepared by centrifugation on Ficoll-Paque (Pharmacia, Piscataway, NJ).[21]

Dye-mediated photolysis. Single-cell suspensions of neuroblastoma cells were prepared by incubating subconfluent monolayers briefly with trypsin-EDTA (0.5 g trypsin and 0.2 g EDTA/L Hanks' balanced saline; GIBCO, Grand Island, NY) and filtering the detached cells through a nylon screen (HD3-15; Tetko, Elmford, NY) to remove cell aggregates. The filtered cells were washed once with HEPES-buffered (10 mmol/L, pH 7.4) α-medium supplemented with 5% FBS and resuspended at a density of 1×10^6/mL in HEPES-buffered α-medium supplemented with 15% FBS, penicillin (10 U/mL), and streptomycin (10 μg/mL). Cell viability by trypan blue exclusion was $\geq$98%. Mononuclear marrow cells were suspended in the same medium at a concentration of 5×10^6/mL. MC 540 (Eastman, Rochester, NY) was added from a 1 mg/mL stock solution in 50% ethanol to a final concentration of 15 μg/mL. Clear polystyrene tubes (15-mm diameter, Corning, Corning, NY) containing the cell suspensions were placed into the center of a circular array (40-cm diameter) of 10 fluorescent light bulbs (Champion F15T8/D, 61 cm long). The cell suspensions were swirled manually every 10 minutes to prevent the cells from settling. Samples were removed at 15-minute intervals to determine the surviving fraction of in vitro clonogenic cells. The photosensitization process was stopped by washing the cells twice with HEPES-buffered α-medium supplemented with 5% FBS and antibiotics. This and all subsequent manipulations were carried out in the dark or under subdued lighting.

Bioassays. CFU-GEMM from normal human marrow were assayed as described by Messner and Fauser.[22] Each 35-mm Petri dish contained 10^5 nucleated marrow cells and 1 mL of Iscove's modified Dulbecco's medium (GIBCO) supplemented with 30% FBS bovine serum, 0.9% methylcellulose, 5×10^{-5} mol/L of 2-mercaptoethanol, 1 U of sheep plasma erythropoietin (step III, Connaught Laboratories, Willowdale, Ontario, Canada) and 5% phytohemagglutinin-stimulated leukocyte-conditioned medium. Cultures were incubated for 14 days at 37 °C in a humidified atmosphere of 5% CO_2 in air. Mixed colonies were scored in situ with an inverted microscope. Selected colonies were removed with a finely drawn pipette and stained with benzidine and Wright's-Giemsa to verify their cellular composition.

Two different methods were used to assay in vitro clonogenic neuroblastoma cells.

The first method was used for anchorage-independent cells. Approximately 400 untreated or up to 80,000 photosensitized cells were plated in nonadhesive 35-mm Petri dishes (Greiner, Nuertingen, FRG) containing 1 mL of α-medium supplemented with 20% heat-inactivated FBS and 0.9% methylcellulose (4,000 cPs, Fluka, Buchs, Switzerland) and incubated at 36 °C in a humidified atmosphere of 5% CO_2 in air. Two weeks later, colonies estimated to consist of at least eight cells were scored in situ with an inverted microscope. Plating efficiencies were 32% for IMR-32 and 44% for SK-N-MC cells. This method yielded well-defined, compact colonies that were easy to score even at high densities. It was, however, only applicable to IMR-32 and SK-N-MC cells.

The second method was primarily used for the assay of anchorage-dependent SK-N-SH cells: Approximately 200 untreated or up to 80,000 photosensitized cells were plated in 35-mm tissue culture dishes (Corning) containing 2 mL of α-medium supplemented with 20% heat-inactivated FBS. After 2 weeks at 36 °C in a humidified atmosphere of 5% CO_2 in air, the cultures were fixed by the addition of 0.2 mL of a 25% solution of glutaraldehyde in water. The fixed cells were then stained with Wright's-Giemsa, washed with water, air dried, and evaluated with an inverted microscope. The plating efficiency of SK-N-SH cells was 22%.

SK-N-MC and IMR-32 cells that were routinely assayed in methylcellulose cultures were assayed at least once on adhesive tissue culture dishes to establish that both colony assays yielded equivalent survival curves. Plating efficiencies were lower than in methylcellulose (18% and 31% for IMR-32 and SK-N-MC cells, respectively), but the shape of the survival curves was identical.

Double logarithmic plots of the number of colonies formed as a function of the number of cells plated could be fitted with a straight line with a slope of Δ log (colony count)/Δ log (cells plated) = 1[23], indicating that the colony assays were linear down to limiting dilutions, and that colonies were of clonal origin.

RESULTS

Photosensitization of neuroblastoma and normal bone marrow cells progressively reduced the number but not the size of colonies formed. At the time of evaluation, cultures set up with heavily photosensitized neuroblastoma cells contained few or no cells. However, they contained much cell debris, indicating that MC 540-mediated photosensitization killed and eventually lysed susceptible cells rather than just slowing their growth.

Extensive inhibition of colony formation required exposure to both, dye and light (Table 1). Incubation with dye in the dark had no effect. Exposure to light in the absence of dye reduced the concentration of in vitro clonogenic neuroblastoma cells. However, the reduction was minimal as compared with the reduction achieved by simultaneous exposure to dye and light (Table 1).

All three neuroblastoma cell lines were more sensitive to MC 540-mediated photolysis than were CFU-GEMM from normal bone marrow (Fig 1). Exposure to light for 90

Table 1. Effects of MC 540 and Light on In Vitro Colony Formation by Neuroblastoma Cells

	Cell Line		
Conditions	SK-N-SH	SK-N-MC	IMR-32
Untreated	54.25 ± 2.84	187.25 ± 2.78	135.75 ± 3.66
Light, 90 min	39.50 ± 3.50 (P = .017)	132.00 ± 2.48 (P < .001)	44.25 ± 1.75 (P < .001)
MC 540, dark	53.50 ± 4.66 (P = .895)	214.50 ± 11.08 (P = .054)	137.25 ± 7.73 (P = .867)
MC 540, light, 90 min	0.0425 ± 0.0149 (P < .001)	0.0100 ± 0.0058 (P < .001)	0.0025 ± 0.0025 (P < .001)

MC 540, merocyanine 540.

Data are expressed as mean colony counts of four replicate culture dishes ± SEM. Only simultaneous exposure to both MC 540 and light caused a drastic reduction of colony formation. P values in parentheses: two-tailed Student's t test.

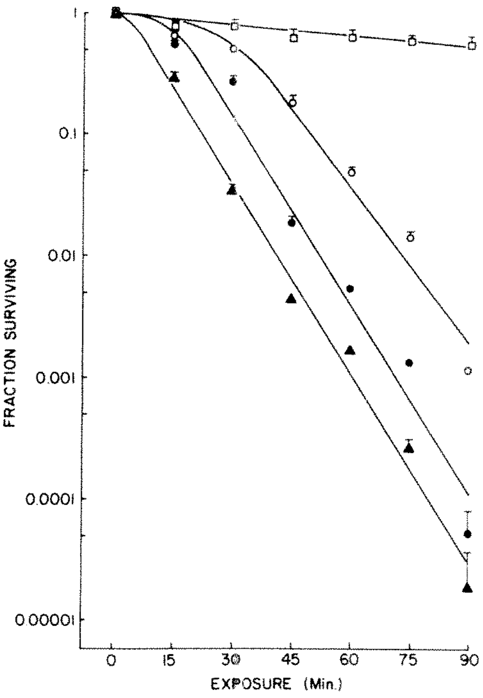

Fig 1. Representative example of the photosensitization of multipotent hematopoietic progenitor cells (CFU-GEMM; □), and three neuroblastoma cell lines, SK-N-SH (○), SK-N-MC (●), and IMR-32 (▲), respectively. All data points represent mean colony counts of four to eight replicate culture dishes. Vertical bars indicate SE. Colony counts at zero time point were 8.7 ± 1.7 (CFU-GEMM), 88 ± 9.4 (SK-N-SH), 201 ± 20.9 (SK-N-MC), and 137 ± 11.2 (IMR-32) respectively. SK-N-SH cells were assayed on adhesive tissue culture dishes; IMR-32 and SK-N-MC cells were assayed in nonadhesive Petri dishes.

minutes reduced the concentration of in vitro clonogenic SK-N-SH, SK-N-MC, and IMR-32 cells 1,000-fold, 10,000-fold, and 50,000-fold, respectively, yet preserved 55% of CFU-GEMM.

Colonies formed by IMR-32, SK-N-MC, and SK-N-SH cells were heterogeneous with respect to size and the morphologic appearance (eg, number and length of neuronal processes) of the cells they contained. A similar degree of heterogeneity was evident in both untreated and photosensitized cultures. Colony heterogeneity was therefore not a result of distinct subpopulations of colony-forming cells that could be distinguished by their sensitivity to MC 540-mediated photosensitization.

When survival curves were plotted semilogarithmically, the portion of the curve to the right of the plateau (Fig 1) could be fitted by a single straight line, indicating that most colony-forming cells of a given neuroblastoma line were about equally sensitive to dye-mediated photosensitization. Subpopulations that were significantly less sensitive than the majority of cells would have resulted in biphasic or multiphasic survival curves. Small subpopulations of photoresistant cells would have been detected most readily in the IMR-32 line where the survival curve spanned >4 logs.

Because the neuroblastoma cells were obtained from cultures in exponential growth phase, they contained cells in all phases of the cell cycle. The linear survival curves thus also indicate that in these three neuroblastoma cell lines all stages of the cell cycle were photosensitive. Again the argument is strongest for the IMR-32 line in which the survival curve spanned >4 logs.

DISCUSSION

MC 540 is an amphipathic fluorescent dye.[24] In the absence of serum, it binds indiscriminately to the plasma membrane of all cells. However, in the presence of serum which acts like a competitive substrate with binding sites of intermediate affinity, the dye binds preferentially to cells with high-affinity binding sites for dye molecules. High-affinity dye-binding sites abound on electrically excitable cells, leukemic cells, and certain classes of immature blood cells.[25-28] Some authors have suggested that MC 540 binds preferentially to disordered[29] or cholesterol-free[30] domains in the outer leaflet of the lipid bilayer. Other authors favor the view that a cell's affinity for MC 540 is a function of the electrical properties of its plasma membrane.[25,26] The phototoxic reaction is not yet fully understood. It probably involves the formation of reactive oxygen species,[24] and plasma membrane lipids may be their primary target (lipid peroxidation). Cells that adsorb large amounts of dye tend to be photolysed more rapidly than are cells that bind small amounts of dye,[31] suggesting that a cell's sensitivity to MC 540-mediated photolysis is primarily a function of the density of high-affinity dye-binding sites.

In this article, we show that three human neuroblastomas were markedly more sensitive to MC 540-mediated photolysis than CFU-GEMM from normal human bone marrow. The fact that the three neuroblastoma lines differed significantly with regard to their sensitivity to MC 540-mediated photolysis is not surprising. The three cell lines were derived from different patients and from primary and secondary tumors from different sites. We do not attach too much importance to the observation that the two lines derived from patients who had undergone chemotherapy and radiotherapy were less photosensitive than the line that had been established from an untreated neuroblastoma. Previous experiments with multiple drug-resistant mutant tumor cell lines have shown that drug-resistant tumor cells were usually not less photosensitive than the corresponding wild type of tumor cell line.[31]

The two cell lines derived from metastatic tumors (SK-N-MC and SK-N-SH) happened to be less photosensitive than the line that originated from a primary tumor (IMR-32). Site-specific alterations in the lipid composition of tumor cells have been described (reviewed in ref. 32). It is conceivable that site-specific differences in photosensitivity occur as well.

Exposure to light in the absence of dye reduced the concentration of in vitro clonogenic neuroblastoma cells by 25% to 65% (Table 1). Similar observations have been made with one human leukemia cell line, murine erythroid progenitor cells, and quail neural crest cells.[33,34] The mechanism of this phototoxic effect is unclear. We have some suggestive evidence that dye-independent phototoxicity is at least in part attributable to the small amount of ultraviolet (UV) light emitted by some white light sources. It is also known that daylight fluorescent light can generate toxic photoproducts in tissue culture medium which can rapidly and irreversibly damage susceptible cells.[35]

Although CFU-GEMM are primitive progenitor cells, they are probably not identical with the pluripotent hematopoietic stem cell. Our data, therefore, do not prove that the human pluripotent hematopoietic stem cell is photoresistant. Such proof could only be derived from the hematologic reconstitution of patients who have received marrow-lethal cytoreductive therapy. However, the striking parallels that exist between the photosensitivities of hematopoietic progenitor cells in mice and humans suggest that the pluripotent hematopoietic stem cell compartment in humans is photoresistant. All classes of progenitor cells that have been tested so far follow the same rank order of sensitivity[33,36-38] in mice and humans. Late erythroid progenitors are the most sensitive cells, followed in order of decreasing sensitivity by early erythroid progenitors, granulocyte/macrophage progenitors, and day 12 spleen colony-forming cells (CFU-S_{12}) (in the mouse) and CFU-GEMM (in humans), respectively. In the mouse, the pluripotent stem cell compartment appears to be even less sensitive than CFU-S_{12},[17,39] because marrow grafts that are essentially depleted of CFU-S_{12} are still capable of rescuing lethally irradiated hosts. By inference, we would therefore expect the human pluripotent hematopoietic stem cell to be at least as photoresistant as CFU-GEMM.

If the high photosensitivity of experimental neuroblastomas can be confirmed in spontaneous tumors, our findings have implications for the purging of autologous remission marrow grafts. Despite our limited understanding of the molecular mechanism of MC 540-mediated photosensitization, it seems reasonable to speculate that the parameters that define a cell's sensitivity to MC 540-mediated photosensitization are quite different from those that define affinity for lectins or antibodies, behavior in density gradients or electrical fields, or susceptibility to most antineoplastic drugs. We, therefore, expect to see little cross-resistance if dye-mediated photosensitization is used in combination with other purging methods. This point may be relevant to the treatment of patients with relapsed neuroblastomas which frequently contain drug-resistant clones.

Stimulation of Persisting Colonies in Agar Cultures by Sera From Patients With CML and AML

By Ross D. Brown, Edna Yuen, Harry Kronenberg, and Kevin A. Rickard

Cord plasma contains colony-stimulating activity (CSA) which stimulates the in vitro clonal growth of neutrophils, eosinophils, macrophages, erythrocytes, and persisting mast cells in semisolid cultures. Analysis of day 35 colonies in agar cultures was found to be a suitable means of demonstrating this activity and discriminating between it and granulocyte-macrophage colony-stimulating factor (GM-CSF). Serum (10%) from patients with acute and chronic myeloid leukemia (AML and CML) was added to normal human bone marrow cultures to search for similar activity in these patient's serum. Although the number of colonies on day 12 (predominantly neutrophils and macrophages) was not significantly different from the number of colonies in cultures containing normal serum, the number of colonies increased 500% in cultures containing CML serum on day 35. Serum from patients with AML during regeneration also stimulated an increased number of colonies on day 35. Although both eosinophil and mast cell colonies were still present on day 35, only mast cell colonies persisted for 150 days. On day 35, cultures containing 10% CML serum contained predominantly eosinophil colonies (84%), whereas cultures containing AML serum contained predominantly mast cell colonies (76%). Although serum contains various CSFs, the specific factor which stimulates persisting mast cell colonies may be the human equivalent of murine persisting (P) cell-stimulating factor (Multi-CSF).

© *1986 by Grune & Stratton, Inc.*

THE PRODUCTION and function of granulocytes is controlled by a group of specific glycoproteins known as colony-stimulating factors (CSFs) because of their ability to stimulate hematopoietic precursor cells to form colonies in semisolid medium. Four murine granulocyte-macrophage CSFs (GM-CSF, G-CSF, M-CSF, and Multi-CSF) have been identified and purified.[1-4] cDNAs for murine GM-CSF[5] and murine Multi-CSF, also known as interleukin-3 (IL-3),[6] have been isolated and transfected into cells to produce recombinant CSFs. Purified preparations of both natural and recombinant human GM-CSF have also been produced.[7]

The term persisting (P) cell has been given to a specialized subset of murine mast cells[8] that are capable of prolonged growth in vitro when cultured in the presence of a specific hematopoietic growth factor called P cell–stimulating factor (PSF). PSF is now considered to be identical to a number of other multilineage hematopoietins including burst-promoting activity,[9] IL-3,[4] and Multi-CSF.[10] Murine P cells are mononuclear cells with large metachromatic granules rich in histamine.[9] Variant P cells have arisen that grow in the absence of exogenous PSF by producing autogenous PSF and, unlike the parental P cells, are tumorigenic in vivo.[11] It has been suggested that the autogenous production of PSF may be a mechanism for the malignant transformation of hematopoietic cells.[11,12]

We recently reported the existence of persisting mast cell-like colonies in cultures of human cord blood cells.[13] In this report, we demonstrate that human bone marrow cells in the presence of cord plasma can also grow persisting colonies and that these persisting colonies are the result of colony-stimulating activity (CSA) other then GM-CSF. We also report the relative concentration of this CSA in the serum of patients with acute and chronic myeloid leukemia (AML and CML).

MATERIALS AND METHODS

Sample collection. Bone marrow samples were collected into sterile 5-mL plastic tubes containing 100 IU of heparin after informed consent was obtained from all subjects. Peripheral blood (adult and cord) was collected into 10-mL plastic tubes containing 125 IU of heparin. Plasma was removed after centrifugation and stored at -20 °C.

Agar cultures. Marrow samples were spun at 150 to 200 g for 15 minutes. The plasma and buffy coat were removed and washed in Hanks' balanced salt solution (HBSS) (CSL, Melbourne). Cells were cultured at 2×10^5 cells per milliliter in 0.3% agar medium (McCoys) (GIBCO, Grand Island, NY) as described previously.[14-15] Cultures were stimulated with either 10% giant cell tumor-conditioned medium (GCT-CM) (GIBCO), 10% cord plasma or a combination of two of these factors. Petri dishes were incubated at 37 °C in a humidified atmosphere containing 7.5% CO_2. Agar cultures were kept hydrated for long incubation periods by bubbling air/CO_2 through a 4-L water bath in the bottom of a relatively small incubator (National Model 3221, USA).

Each type of colony had a typical appearance that could be determined with a dissecting microscope (Nikon Model 85615, Tokyo). Confirmation studies were performed on several hundred colonies by removing individual colonies with a Pasteur pipette, squashing them on a slide, and staining them with either May-Grunwald-Giemsa, Astra blue, or the specific histamine stain *o*-phthalaldehyde.[16]

BFU-E assay. The erythroid burst assay was performed as previously described.[17] One-milliliter plasma clot cultures were established in NCTC-109 (GIBCO) with 10% beef embryo extract (GIBCO), 10% bovine serum albumin (BSA) (Sigma, St. Louis), 25% fetal calf serum (FCS) (Flow, Sydney), 15% horse serum (CSL, Melbourne), 10% bovine citrated plasma (Sigma), and 5×10^5 nucleated cells. Cultures with and without 10% cord serum were placed in 35-mm Petri dishes without erythropoietin and incubated for 15 days at 37 °C in a humidified incubator with 7.5% CO_2.

RESULTS

Figure 1A shows a 35-mm Petri dish containing persisting (day 64) colonies in agar cultures stimulated by GCT-CM

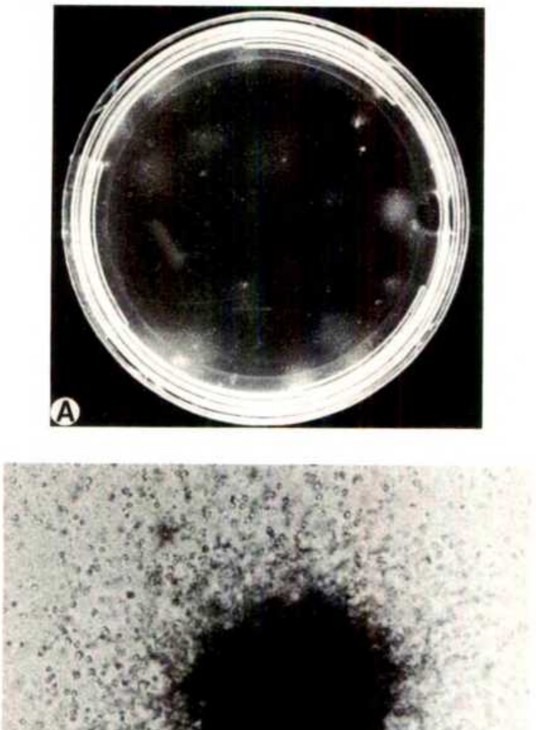

Fig 1. **(A) Petri dish (35 mm) containing persisting colonies stimulated by both GCT-CM and cord plasma on day 64 of culture. (B) Typical day 35 eosinophil colony. (C) Typical day 35 mast cell colony.**

and cord plasma. In cultures of cord blood, colonies grew up to 8 mm in diameter by day 64. Because of the addition of fresh agar medium every month, persisting colonies have continued in vitro for >150 days. Figure 1B shows a typical day 35, dark and compact eosinophil colony; Fig 1C shows a typical, day 35, mast cell colony containing loosely packed, large clear cells. The identity of the mast cells was confirmed by staining with Astra blue and the specific histamine immunofluorescent stain *o*-phthalaldehyde.[16] Mixed colonies of mast cells and eosinophils occurred, but at a very low frequency. Detailed morphologic studies of day 12 neutrophils and day 35 eosinophils and mast cells have been previously demonstrated.[13]

The total number and type of colonies in GCT-CM stimulated normal human marrow cultures with and without 10% cord plasma were determined on both day 12 and 35. A total of 40 different cord plasma samples and 16 different normal marrow samples were studied. Table 1 shows some typical results from four different normal marrows each stimulated by three different cord plasmas. Bone marrows 1 and 2 were both stimulated by the same three cord plasmas, yet produced a different proportion of eosinophil and mast cell colonies. In all our experiments, colonies of mast cells and eosinophils continued to grow in vitro if stimulated by both cord plasma and GCT-CM, whereas neutrophil colonies degenerated and disappeared soon after their peak on day 12. Cord plasma alone stimulated colonies on day 35 only if there was significant marrow autostimulation (eg, BM 3). The dose–response curve for the concentration of cord plasma was sigmoid but linear for the number of cells cultured.

The number of colonies in GCT-CM stimulated normal human bone marrow cultures containing 10% serum from patients with AML ($N = 4$), AML in remission ($N = 9$), and CML ($N = 14$), as compared with normal control sera ($N = 9$) when counted on day 12 is shown in Fig 2. There was a fairly wide spread in the overall results; however, the mean and the range was similar for each group. Eight different normal bone marrow samples were used to test these AML and CML sera.

Figure 3 illustrates the number of colonies in the same cultures as in Fig 2 when recounted on day 35. There was a >500% increase in the mean number of persisting colonies in the cultures (day 35) containing CML serum (mean number of colonies = 25.2) as compared with normal serum (mean number of colonies = 4.8). Serum from patients with AML in early remission also stimulated an increased number of persisting colonies. Cultures with AML or CML sera but without GCT-CM had very few or no colonies on day 35.

The type of cells in day 35 normal marrow cultures containing 10% patient's serum and 10% GCT-CM is illustrated in Fig 4; 84% of the colonies in cultures containing CML serum were eosinophilic, whereas 76% of the colonies in cultures containing nonremission AML sera were mast cell colonies. Although eosinophil colonies were still present on day 35 of these cultures, only mast cell colonies persisted for periods of several months. The cellular integrity of eosinophils in 35-day-old cultures was deteriorating. Consistent eosinophil/mast cell ratios were observed within each group of patients when different marrow samples were used with the same test sera and also when the same marrow was used to test sera from different patient groups.

There was a prolific growth of erythroid bursts in BFU-E cultures of normal bone marrow cells without exogenous erythropoietin but containing 10% cord plasma. In control cultures without cord plasma, virtually no growth occurred.

Table 1. Effect of Cord Plasma on Colony Growth From Four Different Normal Human Marrow Samples

		Number of Colonies per 2 × 10⁵ Marrow Cells

Results are expressed as mean ± SD.

GCT-CM, giant cell tumor-conditioned medium; BM, bone marrow; CP, cord plasma; Auto, autostimulated; Neut, neutrophils; Mono, monocytes; Mast, mast cells; Eosin, eosinophils.

*Mean of 3 plasmas.

DISCUSSION

Normal human bone marrow progenitor cells have been stimulated to produce colonies of eosinophils and mast cells in 35-day-old agar cultures by a CSA that we first described in cultures of cord blood cells.[13] The results have shown that this CSA is not GM-CSF and is present in the serum of patients with CML at a concentration which is, on average, 500% higher than in normal serum. Patients with AML in early remission also tended to have an increased concentration of this CSA. Although the stimulation of these additional colonies may be owing to more than one specific CSF, we suggest that the persisting mast cell colonies may be the human equivalent of the murine P cell,[8] and the CSA involved may be human PSF, otherwise known as IL-3 or Multi-CSF.[4,10] If this suggestion is true, our results indicate that in the serum of patients with CML there is a 500% increase in the concentration of a factor that is known to stimulate stem cell self-renewal. This, together with other factors such as a decreased release of neutrophil-derived lactoferrin,[15] may well cause the characteristic expansion of the myeloid stem cell pool in CML. Future studies should include a biochemical characterization of this CSA and isolation of cDNA clones.

Studies involving the addition of serum from patients with leukemia to normal marrow cultures were performed by several groups more than a decade ago.[18,19] Like those described in the results in Fig 2, these cultures were counted after 12 to 14 days of incubation and thus were detecting GM-CSF and GM-CSF inhibitor levels in leukemia. Neither these previous studies nor our results in Fig 2 produced results of any real significance.

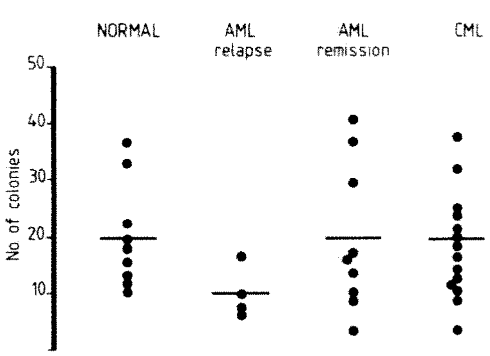

Fig 2. The number of colonies per 2 × 10⁵ cells plated in GCT-CM–stimulated normal human bone marrow cultures containing 10% serum from patients with acute myelogenous leukemia (AML), AML in remission, and chronic myelogenous leukemia (CML) as compared with a normal control group on day 12.

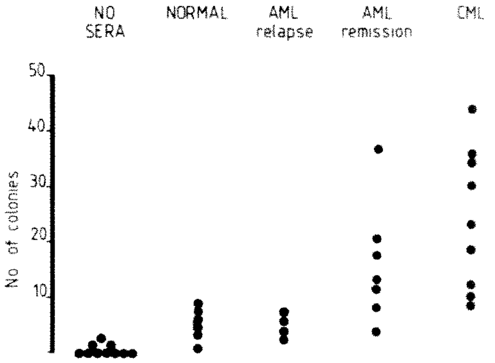

Fig 3. The number of colonies per 2 × 10⁶ cells plated in normal GCT-CM–stimulated cultures containing 10% serum from patients with acute myelogenous leukemia (AML), AML in remission, and chronic myelogenous leukemia (CML) as compared with a normal control group on day 35. The same cultures were counted as in Fig 2.

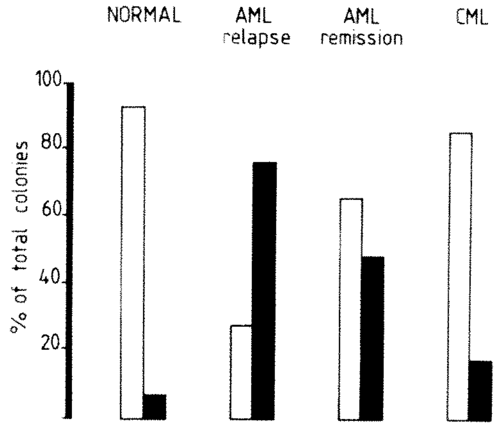

Fig 4. The proportion of eosinophil and mast cell colonies in day 35 normal bone marrow cultures containing 10% serum from patients with acute myelogenous leukemia (AML), AML in remission, and chronic myelogenous leukemia (CML). ☐, Eosinophil; ■, mast.

The fact that day 35 colonies in cultures containing CML sera were predominantly eosinophilic whereas day 35 colonies in cultures containing AML serum were predominantly mast cells is an interesting phenomenon that is difficult to explain. Although the eosinophil/mast cell ratios were found to be relatively consistent for each AML or CML sera tested (Fig 4), there was considerable variation in the eosinophil/mast cell ratio when cord plasma was tested (Table 1). The observations that different cord plasma samples could stimulate the same proportion of eosinophil and mast cell colonies in day 35 cultures of the same normal marrow cells, yet a single cord plasma sample did not necessarily stimulate the same proportion of eosinophil and mast cell colonies when used in cultures of different normal marrow cells (Table 1), suggests that the specific line of differentiation is determined not only by the exogenous stimulating activity but also by other factors, including the target cells within the marrow cell population. Perhaps future studies may reveal that AML and CML have a similar etiology in terms of oncogenesis, with the transforming gene of a tumor-inducing virus infecting stem cells at various levels of differentiation. Thus, subtle differences in gene rearrangements which involve the expression of growth factors may produce various forms of myeloid leukemia.

Fucose Binding Lectin for Characterizing Acute Myeloid Leukemia Progenitor Cells

By Ruud Delwel, Ivo Touw, Freek Bot, and Bob Löwenberg

The reactivity of acute myeloid leukemia cells (AML) was determined in 29 patients using the fucose binding lectin *Ulex europaeus* agglutinin (UEA) as surface marker. We show a marked heterogeneity in the UEA-binding abilities of the cells in these patients as determined by fluorescence analysis of the blasts labeled with the UEA coupled to the fluorescent molecule FITC. The results suggest a correlation between the capability of AML blast cells to bind UEA and cytologic maturation, because in 1 of 10 M1, 3 of 8 M2, 6 of 8 M4, and 1 of 3 M5 cytology types UEA binding to the leukemic cells was apparent. In 13 cases, the cells gave rise to colonies in vitro. The amount of UEA binding to AML colony-forming cells (AML-CFU) was determined by cell sorting and subsequent colony culture of UEA-negative, intermediately positive, and highly fluorescent cells. AML-CFU from none of the four patients with M1 cytology were UEA positive, whereas they showed intense reactivity with the lectin in 1 of 4 cases with M2 cytology and in all 4 cases of M4. In these five cases with strongly UEA positive AML-CFU, the fluorescence distribution of the colony formers differed from that of the total leukemia population, indicating that AML-CFU represent a subpopulation of AML cells with specific UEA-binding properties. Normal bone marrow myeloid and multipotential colony-forming cells (CFU-GM, CFU-GEMM) showed low or no binding of UEA. UEA-FITC appears a useful reagent for membrane analysis of AML-CFU. In certain cases, UEA-FITC labeling may be applied to discriminate AML-CFU from normal hematopoietic progenitors.

© 1986 by Grune & Stratton, Inc.

SEVERAL STUDIES have dealt with the detailed phenotyping of acute myeloid leukemia colony-forming cells (AML-CFU) in relation to normal bone marrow colony formers (CFU-GM, CFU-GEMM).[1-3] The results of those studies indicate that AML-CFU can be recognized as the leukemic counterparts of normal hematopoietic progenitor cells. These investigations were performed with monoclonal antibodies, which have become the most common tools to identify surface phenotypes.[4-14]

Lectins may also be of value to detect surface antigens. For example, the fucose-binding lectin from *Lotus tetragonolobus* (FBL-L) has been shown to react with human myeloid cells.[15-18] The amount of cellular binding of the lectin increases progressively from myeloblasts toward mature granulocytes; monocytes show intermediate reactivity. CFU-GM mainly belong to the low FBL-L–binding bone marrow fraction. No information exists on the usefulness of the lectin for analysis of AML-CFU.

In the present study, we labeled AML blasts with the fucose binding lectin (FBL) *Ulex europaeus* agglutinin coupled to fluorescein-isothiocyanate (UEA-FITC) to determine whether UEA-binding to AML-CFU is different from that of normal CFU-GM and CFU-GEMM. We also compared UEA binding patterns of AML-CFU with that of the total AML blast population and with morphological classification of AML according to the criteria of the French-American-British (FAB) group.[19]

It is shown that: (a) in certain cases, UEA binding to AML-CFU is markedly discrepant from that of normal CFU-GM and CFU-GEMM; (b) binding patterns of AML-CFU can be distinguished from those of total blast populations; and (c) UEA binding capacity of AML-CFU is positively correlated to cytologic (FAB) maturation.

MATERIALS AND METHODS

Cell separation. Cells from 29 patients with newly diagnosed AML and from three subjects without hematological disease were studied. AML cytology was classified according to the FAB criteria.[19] All individuals had given consent to donate bone marrow. AML blasts from bone marrow or peripheral blood were separated to >97% purity following discontinuous bovine serum albumin (BSA) density fractionation and E rosette sedimentation.[20-22] The cells were then cryopreserved in aliquots of 30 × 10^6 cells in 7.5% dimethyl sulfoxide (DMSO) and 20% fetal calf serum (FCS) using a controlled freezing apparatus and storage in liquid nitrogen as described.[23] Normal bone marrow cells were recovered from the interface after Ficoll-Isopaque centrifugation.[24]

Colony cultures for AML-CFU, CFU-GM, and CFU-GEMM. Colonies from AML cells were cultured in the PHA-leukocyte feeder (PHA-LF) system.[20,21,25] Colonies in this system from purified blasts are always of leukemic nature as indicated by morphology, immunophenotypes,[5] and cytogenetic markers.[20,21,25] Myeloid colonies (CFU-GM) from normal marrow were grown in a semisolid culture containing human placenta conditioned medium (HPCM; 20% vol/vol) as a source of colony-stimulating factor (CSF).[26,27]

Mixed colonies (CFU-GEMM) were grown as described by Fauser and Messner with slight modifications.[28] Normal bone marrow cells were cultured in a 1-mL mixture of Iscove's modified Dulbecco's medium (IMDM, GIBCO, Gent, Belgium), 1.1% methylcellulose, 30% autologous heparinized plasma, 7.5% of a medium conditioned by leukocytes in the presence of 1% PHA (PHA-LCM), 1 U sheep erythropoietin per milliliter (step III, Connaught, Willowdale, Ontario, Canada), BSA, transferrin, lecithin, sodium selenite, and 2-mercapto-ethanol. Dishes were incubated at 37 °C and 100% humidity in an environment of 5% CO_2 in air. Colonies were scored at day 15. Mixed colonies were defined as containing red hemoglobinized cells plus at least 5% nonhemoglobinized translucent cells of various sizes. Disputable mixed colonies were always verified cytologically after they were lifted off the plate with a fine-drawn Pasteur pipette.

Labeling of cells with UEA-FITC and FACS. AML blast cells or bone marrow nucleated cells were suspended in phosphate-buffered saline (PBS) containing 5% FCS at a cell concentration of

2×10^7 cells/mL. The suspension was incubated for 30 minutes at 4 °C with 20 μL of UEA-FITC (Polysciences Inc, Warrington, Pa). The cells were then washed three times with PBS and resuspended in PBS with 5% FCS at a cell concentration of 2×10^6 cells per milliliter. Cell sorting was performed on a FACS 440 (Becton Dickinson, Sunnyvale, Calif). Excitation was performed with the laser at 488 nm (0.4 W). For the fluorescence measurements, a 530/30 band pass filter was used. The instrument was calibrated with fluorescent standard beads (1.0 μm and 2.83 μm in diameter) (Polysciences Inc).

Dead cells among the leukemic population were excluded from analysis by elevating the threshold level of the forward light scatter. Fractions of different fluorescence intensity were sorted following a sterile procedure and plated separately in colony culture for determining the number of colony-forming cells as a function of the amount of UEA binding. Usually, between 1.5 to 3.0×10^5 cells per fraction were collected. Sorting rate was between 1,500 and 2,000 cells/second. Data analysis was performed using a Hewlett Packard 86B system.

May-Grünwald-Giemsa staining. After FACS, normal bone marrow cells or peripheral blood cells were suspended in 50% FCS in PBS (4×10^5 cells in 0.1 mL) and centrifuged onto clean glass slides (500 rpm for 5 minutes). The slides were air dried and, after fixation in methanol (1½ minutes), they were stained with May-Grünwald's solution for 3 minutes and then counterstained with 4% (vol/vol) Giemsa in PBS. Slides were then washed and air dried. Differential counts were performed at ×1,000 magnification under oil, counting 250 cells.

RESULTS

UEA-binding to AML-blasts and AML progenitors. The reactivity of purified AML cells to the fluorescent FBL (UEA-FITC) was studied. In 11 of 29 cases, the AML blasts reacted with the lectin (Table 1). The data are indicative of a correlation between the binding of UEA and morphologic maturation of AML cells according to the FAB classification. The blasts of only 1 of 10 patients with AML-M1 cytology were UEA reactive, whereas in 3 of 8 cases of AML-M2, 6 of 8 AML-M4, and 1 of 3 AML M5, the cells showed significant UEA binding.

Of the complete series of patients, in 13 cases the cells were capable of giving rise to colonies in vitro. To determine the quantitative level of surface binding of UEA-FITC to AML-CFU, cells were sorted into separate fractions of varying fluorescence intensity and seeded into PHA-LF. AML-CFU from subjects with a relatively undifferentiated AML morphology, ie, all four M1 cases, showed no or minimal capacity for UEA-binding (Table 2), whereas AML precursor cells from one of four patients with M2 and four of four patients with M4 cytology exhibited high UEA binding. The colony formers of the single patient with acute monoblast leukemia (M5) did not bind detectable UEA to their surface. In Fig 1, four typical examples are given of the fluorescence distribution profiles of AML blast cells and AML-CFU. The cells from three patients also formed colonies in the other culture system, ie, with HPCM as stimulator. The distributions of AML-CFU as assessed in these cultures were found to be identical to those of AML-CFU grown in the PHA-LF method (data not shown).

UEA binding to normal bone marrow cells, CFU-GM, and CFU-GEMM. For comparison, the UEA-binding properties of normal marrow cells, CFU-GM and CFU-GEMM were determined. Figure 1 gives an example of the UEA-FITC fluorescence distribution of Ficoll-separated normal marrow cells and CFU-GM. CFU-GEMM, not plotted, showed essentially identical UEA binding properties as CFU-GM. It is evident from this and the data from the separate experiments shown in Table 2 that low amounts of UEA-FITC bind to the cell surface of normal CFU-GM and CFU-GEMM.

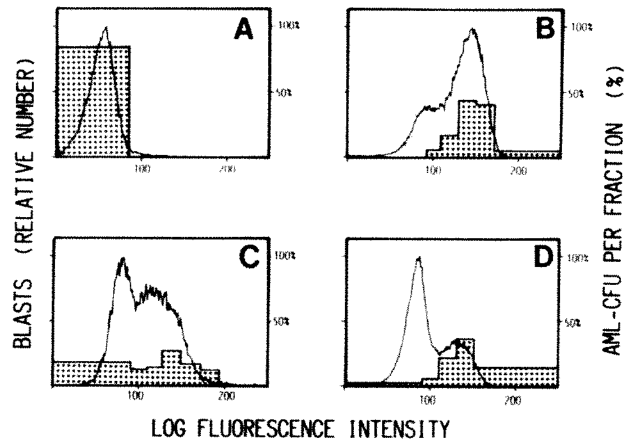

Fig 1. Distribution of acute myelogenous leukemia (AML) blast cells (——) and AML-CFU (▨) as a function of the fluorescence intensity following *Ulex europaeus* agglutinin (UEA)–FITC labeling (four representative profiles). Fractions: 0 through 90; 91 through 110; 111 through 130; 131 through 150; 151 through 170; and 171 through 255. (A) Patient 4 (FAB-M1): AML blasts and AML-CFU are UEA negative. (B) Patient 11 (FAB-M4): heterogeneous quantities of UEA are bound to AML blasts. AML-CFU are recovered from the blast cell fraction, intensively reactive with UEA. (C) Patient 8 (FAB-M2): broad peak of UEA binding indicating cellular heterogeneity. Most AML-CFU are UEA reactive. (D) Patient 12 (FAB-M4): most AML blasts are weakly UEA positive, but most AML-CFU are selectively recovered from the strongly UEA-positive subpopulation.

In addition, the relative density of UEA binding of different marrow cells was determined following cell sorting and subsequent differential counting of the smear (Table 3). Nucleated red cells were highly reactive with the lectin, whereas >50% of the monocytes showed intermediate to strong UEA binding. Only part of the promyelocytes/myelocytes were weakly UEA positive. All other cell types were found in the negative fraction. Peripheral blood monocytes and most of the eosinophils showed high UEA reactivity whereas neutrophilic granulocytes were intermediately positive for UEA. Basophilic granulocytes were equally distributed; lymphocytes were UEA negative.

DISCUSSION

In this study, we examined the reactivity of the UEA to AML blast cells and AML-CFU. The findings were related to the maturation stage of AML (FAB) and to UEA reactivity of normal bone marrow nucleated cells, CFU-GM and CFU-GEMM. Lectin binding to the surface of AML blast cells among the patients (N = 29) showed considerable variability. The cell samples from 18 patients were UEA negative; the blasts from 11 patients were UEA positive. Fluorescence histograms indicate that UEA reactivity is heterogeneously distributed among blasts, indicating subsets with relatively low and high UEA surface binding.

Although the number of cases was limited, a correlation is suggested as regards the capacity of the cells to bind UEA and their morphology. The M1 cases with one exception were negative, whereas cells from three of eight M2 cases and six of eight M4 cases reacted with the lectin. The cells from one of three cases of an acute monoblastic leukemia (M5), showed UEA reactivity. The data are compatible with the results from investigations with FBL-L.[28] In the latter studies, it was demonstrated that 5 of 6 M4 cases and the 1 M2 case reacted with this FBL-L, whereas their 1 M5 case was FBL-L negative. No AML cells classified as M1 were examined in that particular study. FBL-L and UEA are both reactive with α-L fucose. UEA can be washed from the cells with this sugar (data not shown). The reactivity of the two lectins, however, differs somewhat. FBL-L has a higher binding capacity for granulocytes than for monocytes.[16–18] Our results show the opposite for UEA, ie, intense binding to monocytes and an intermediate binding to neutrophilic granulocytes. Studies in larger numbers of patients appear of interest in order to evaluate the usefulness of UEA as a reagent in the classification of AML.

The fluorescence histograms shown in Table 1 reveal three discrete types of reactivity among the leukemias: a group of cases of fully UEA-negative AML (N = 18), a second group of AML containing ~20% UEA-positive cells (N = 4) and a

†Total of each cell type was set at 100%. Recoveries of different cell types from methylcellulose sedimented blood are indicated in parentheses.

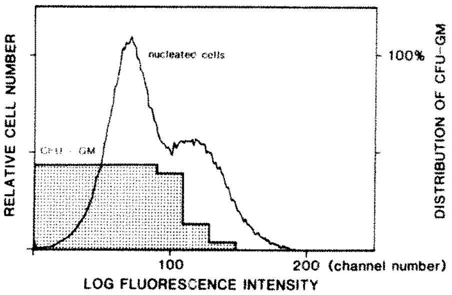

Fig 2. Distribution of normal bone marrow nucleated cells and CFU-GM as a function of fluorescence intensity following *Ulex europaeus* agglutinin (UEA)-FITC labeling. Fractions: 0 through 90; 91 through 110; 111 through 130; 131 through 150; and 151 through 255.

third series of seven cases, in which 100% of the cells reacted with the lectin. Because we had no sufficient cell material to study colony growth among cases of each of these three groups, we were not able to correlate these classes to colony-forming abilities or AML-CFU phenotypes. However, it appeared that of the fully UEA-positive AML cases with colony growth, the majority of the AML-CFU were recovered from the UEA weakly positive fraction in one case and, in the other 5 cases, from the UEA strongly positive fraction.

Sorting experiments using UEA-FITC fluorescence show that in several cases AML-CFU can be recognized as a subgroup of cells with specific lectin-binding properties. This is consistent with the results of immunophenotyping, which have indicated that AML-CFU are frequently different from the total AML population in their antigenic cell surface profile.[9,12,13]

The relation between UEA binding and FAB categories holds up when binding is expressed for the AML-CFU subpopulation. In 4 M1 cases, UEA binding to AML-CFU was low (Table 2), whereas in 1 of 4 M2 and 4 of 4 M4 patients, a high level of UEA binding sites was demonstrated on the cell membrane. Variations in the expression of membrane antigens of AML-CFU have been noticed by different groups.[12-14] Correlations between immunophenotypes of AML-CFU and AML cytology have been established but have provided controversial results. On the basis of the antigenic cell surface structure, Lange and co-workers classified AML-CFU as counterparts of the in vitro multipotential stem cell (CFU-GEMM), "early" CFU-GM or "late" CFU-GM. These investigators did not find a correlation with FAB classification of AML cells.[1] However, using another panel of monoclonal antibodies, Sabbath and colleagues concluded that the antigenic makeup of AML-CFU tended to correlate with the maturation stage of the cells.[2] We demonstrate that CFU-GM and CFU-GEMM were generally UEA negative or weakly positive. We suggest that AML-CFU with little UEA reactivity are generally of a more immature phenotype, whereas AML-CFU with high binding capacities are more differentiated into monocytic directions.

Morstyn and colleagues have shown that early as well as late CFU-GM have low affinity for FBL-L.[18] In our studies, AML-CFU in 5 patients (1 AML-M2, 4 AML-M4) showed high reactivity with the lectin UEA and, in 8 cases, AML-CFU were recovered from the UEA low-reactive or negative fractions. It is possible that the discrepant UEA-binding capacities of AML-CFU and normal colony formers can be exploited in certain cases for recognizing AML clonogenic cells in the bone marrow during complete remission.

Effects of Purified Bacterially Synthesized Murine Multi-CSF (IL-3) on Hematopoiesis in Normal Adult Mice

By D. Metcalf, C.G. Begley, G.R. Johnson, N.A. Nicola, A.F. Lopez, and D.J. Williamson

Normal adult C57BL, BALB/c, and C3H/HeJ mice were injected intraperitoneally three times daily for up to 6 days with 102,000 U (200 ng) per injection of purified, bacterially synthesized, Multipotential colony-stimulating factor (CSF) (Interleukin-3) (rMulti-CSF) and compared with control mice injected with serum/saline with or without added endotoxin (1 ng/mL). Mice injected with rMulti-CSF exhibited tenfold rises in blood eosinophil and twofold to threefold rises in neutrophil and monocyte levels. The spleens from mice injected with rMulti-CSF showed a 50% increase in weight, elevated levels of maturing granulocytes, eosinophils, nucleated erythroid cells and megakaryocytes, and up to 100-fold rises in mast cells. Progenitor cell frequencies in the spleen were elevated sixfold to 18-fold. No significant changes were observed in the marrow. Sixfold to 15-fold rises were observed in peritoneal cell populations of mice injected with rMulti-CSF with evidence of increased peritoneal macrophage phagocytic activity. Livers of C57BL mice, but not of the other strains, exhibited increased numbers of infiltrating hematopoietic cells whereas rises in mast cell numbers were observed in the mesenteric lymph node, skin, and gut in BALB/c and C3H/HeJ mice. Endotoxin was excluded as being responsible for the observed changes except possibly those involving peritoneal macrophage phagocytic activity. The results indicate that the injection of normal mice with rMulti-CSF significantly stimulates the same types of hematopoietic populations as are stimulated in vitro by Multi-CSF and indicate that this and other CSFs should be useful in stimulating hematopoietic repopulation and functional activity in vivo.

IN VITRO STUDIES have documented the existence of a series of specific regulatory glycoproteins able to control the proliferation and functional activity of various murine hematopoietic subpopulations.[1] Prominent among these is the glycoprotein, multipotential colony-stimulating factor (Multi-CSF), also known as interleukin-3 (IL-3),[2,3] hemopoietic cell growth factor (HCGF),[4] burst-promoting activity (BPA),[5] or persisting cell-stimulating factor (PSF).[6] This molecule has been purified to homogeneity either from medium conditioned by WEHI-3B myelomonocytic leukemic cells[2,6] or lectin-stimulated spleen T lymphocytes.[7] The purified molecule has been shown to stimulate: (a) some self-generation by hematopoietic stem cells with, in addition, the formation of various progenitor cells; (b) the clonal proliferation in semisolid cultures of multipotential, granulocytic, macrophage, eosinophil, erythroid, and megakaryocytic progenitor cells to form colonies of differentiating progeny; (c) the proliferation of mast cells; and (d) the survival and proliferation of various continuous hematopoietic cell lines.[1-7]

Studies by two groups resulted in the initial isolation of cDNA clones for Multi-CSF and deduction of the full amino acid sequence of the polypeptide portion of the molecule.[8,9] Expression of biologically active Multi-CSF (IL-3) has been achieved using either monkey COS cells[8-10] or a bacterial expression system.[11] The recombinant Multi-CSF produced in both types of expression system was found to exhibit the various biological activites noted for the purified native molecule[8-13] (D. Metcalf and G.R. Johnson, unpublished data, March 1985).

The broad proliferative actions of Multi-CSF revealed by in vitro studies suggest that this molecule should have many demonstrable effects on hematopoiesis when injected in vivo. However, the minute amounts of native Multi-CSF available from purification of Multi-CSF–containing media have to date prevented any attempt to establish the in vivo effects of injected native Multi-CSF. With the demonstration that bacterially synthesized Multi-CSF exhibits the in vitro biological actions of the native molecule, it has become reasonable to use this recombinant material for initial studies to determine the effects of injected Multi-CSF on hemopoietic populations in vivo.

In the present study, purified, bacterially synthesized, Multi-CSF was injected for up to 6 days into normal adult mice. The results indicated that injected Multi-CSF of this type is able to induce various changes in hematopoietic tissues, in general agreement with expectations from the known actions of Multi-CSF in vitro.

MATERIALS AND METHODS

Bacterially-synthesized Multi-CSF. The recombinant Multi-CSF (rMulti-CSF) used in these studies was a generous gift from Dr J. DeLamarter (Biogen, SA, Geneva). The *E coli* expression system used to generate this rMulti-CSF (IL-3) and the steps used to purify the bacterially synthesized material have been described elsewhere.[11,14] The bacterially synthesized material was subjected to final purification by reverse-phase high-performance liquid chromatography (HPLC) using a Brownlee RP300 (25 cm, 7 mm ID) column. The rMulti-CSF was recovered using an increasing gradient of acetonitrile (1%/min). The linear gradient was formed at 1 mL/min over 60 minutes with aqueous trifluoroacetic acid (0.15% vol/vol) as a primary solvent and acetonitrile (60% vol/vol) in trifluoroacetic acid (0.1% vol/vol) as a secondary solvent, using a Beckman liquid chromatograph. A single major peak of optical density was observed, and sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of the peak fraction demonstrated

the presence of a single silver-staining band with a mol wt of 16,000. The peak fraction (1 mL) from the HPLC column was diluted in 10% C57BL mouse serum/saline and passed through a Sephadex G-25M (PD-10, Pharmacia, Uppsala, Sweden) column to remove residual acetonitrile.

After passage through the PD-10 column, the fraction containing rMulti-CSF was diluted in 10% C57BL mouse serum/saline to a final concentration of 200 ng rMulti-CSF per 0.2 ml (102,000 U/0.2 mL).

Material for injection into control mice was saline containing 10% C57BL serum or this material with added endotoxin (lipopolysaccharide W, *E coli* 0111:B4) Difco Laboratories, Detroit) (final concentration, 0.25 ng/mL or 1 ng/mL in serum/saline).

Tests for endotoxin levels in the rMulti-CSF and control preparations used for injection were performed using the Limulus assay[15] (Limulus amebocyte lysate, Whittaker MA Bioproducts, Walkersville, Md) prior to, and following, each series of injections (Table 1).

Mice. Mice used (3-month-old male and female C57BL/6fJ/WEHI, BALB/c/An/Bradley/WEHI or C3H/HeJ mice maintained in our institute) were matched for sex and body weight in each experiment. Mice were reared under specific pathogen-free conditions and then were held in conventional animal rooms for 6 weeks before use.

Injection schedule. Mice were injected intraperitoneally (IP) with 0.2 mL of rMulti-CSF (102,000 U per injection) or 0.2 mL of serum/saline or serum/saline containing endotoxin. Injections were performed three times daily at 0800, 1600, and 2200 hours. All analyses were performed commencing at 0900, the last injection being at 2200 the preceding evening.

WBC and hematocrit estimations. Mice were anesthetized with ether and orbital plexus blood obtained using 50-μL micropipettes. No mouse was examined on more than one occasion to avoid misleading cell counts from previously damaged and/or inflamed vessels. WBC counts were performed using hemocytometers and differential cell counts performed on blood films stained with May Grünwald-Giemsa. Hematocrit estimations were performed using microhematocrit tubes and reticulocyte counts performed on blood films stained with Cresyl blue.

Examination of tissues. After white cell counts were performed, mice were reanesthetized with ether, and the peripheral blood was collected from the axillary vessels into heparinized tubes. Following death of the mice from exsanguination, 2 mL of saline was injected IP into each mouse and, after gentle massage of the abdominal cavity, the peritoneal wall was opened and as much fluid as possible was collected with a sterile pipette.

Bone marrow cells were collected from one intact femur shaft, and the spleen was removed aseptically. Portions of the following tissues were taken for histological examination after fixation in 10% formalin in saline: spleen, kidney, liver, mesenteric node, small bowel adjacent to the mesenteric node, lung, heart, skin, and thymus. All sections were prepared in duplicate and stained with hematoxylin and eosin or, for mast cell enumeration, with Alcian-blue-safronin. Cytocentrifuge preparations were made of peritoneal, bone marrow, and spleen cell suspensions and stained with May Grünwald-Giemsa.

Bioassay of rMulti-CSF levels. Levels of rMulti-CSF in injected material, serum, or peritoneal fluid were assayed in serial twofold dilutions in 1 mL agar-medium cultures[1] using either 75,000 C57BL bone marrow cells or 300 32D cells, selectively responsive only to stimulation by Multi-CSF.[16] Cultures were incubated for 7 days at 37°C in a fully humidified atmosphere of 10% CO_2 in air. Colony formation (clones > 50 cells) was scored at ×35 using a dissection microscope. Units of CSF per milliliter were calculated from the linear portion of the dose–response curve, 50 U being the concentration stimulating the formation of half-maximal numbers of colonies.

Assay of progenitor cell levels in injected mice. Dispersed cell suspensions were prepared from femoral marrow, a portion of the spleen, and a portion of the peritoneal cavity cells. Assays were performed in 1-mL agar cultures in 35-mm Petri dishes using 50,000 spleen or peritoneal cells or 25,000 marrow cells per culture. The medium used was Dulbecco's modified Eagle's medium (DMEM) with a final concentration of 20% fetal calf serum (FCS) and 0.3% agar.[1] Colony formation was stimulated by addition of 3,200 U of GM-CSF semipurified from mouse lung conditioned medium.[17] Cultures were incubated for 7 days in a fully humidified atmosphere of 10% CO_2 in air, and colony formation (clones > 50 cells) was scored at ×35 using a dissection microscope.

For CFU-E, BFU-E and mixed-erythroid CFC assays, 100,000 spleen or 50,000 bone marrow cells were cultured in 1-mL cultures containing 0.9% methylcellulose (Fluka, Buchs, Switzerland), Iscove's modified Dulbecco's medium (GIBCO, NY) 60 μg/mL of penicillin, 100 μg/mL streptomycin, 5×10^{-5} mol/L of 2-mercaptoethanol, and 20% vol/vol FCS. Erythroid colony formation was stimulated by the addition of 1.6 U human urinary erythropoietin (specific activity 10 to 2,000 U/mg)[18] for CFU-E-derived colonies and 1.6 U erythropoietin plus 0.1 mL of pokeweed mitogen-stimulated spleen-conditioned medium[19] for BFU-E and Mix-CFC colony formation.

Quantitative estimation of tissue content of megakaryocytes and mast cells. Camera lucida drawings of the spleen, mesenteric node, skin, and gut sections were traced on bond paper at ×12 magnifications, and the organ outline was cut out and weighed. Most of the organ drawings were between 100 and 350 mg. After total megakaryocytes or mast cells in the entire section were counted, the comparative number of cells per organ was determined by the following calculation: number of cells times organ weight in milligrams per drawing weight in milligrams or, in the case of skin and gut, number of cells times 100 per drawing weight in milligrams.

Phagocytosis assays using blood neutrophils and peritoneal cells. Heparinized blood was pooled from the four mice in each experimental group, as were harvested peritoneal cells. Blood neutrophils were enriched by centrifugation of the heparinized blood on a two-layer discontinuous density gradient of hypertonic Metrizamide (Nyegaard A/C, Oslo). Blood was mixed with an equal volume (1 mL) of medium containing 10 U/mL of heparin and loaded onto a gradient containing 2 mL of 18.5% and 2 mL of 20% Metrizamide.

Table 1. Assay for Endotoxin in rMulti-CSF Preparation Used for Injection

Material Assayed	Coagulation With Dilution of						
	1:1	1:2	1:4	1:8	1:16	1:32	1:64
rMulti-CSF 100,000 U/0.2 mL in serum/saline	—	—	—	—	—		
Serum/saline	—	—	—	—	—		
Standard endotoxin 1 ng/mL	+	+	+	+	±	—	—
Standard endotoxin 1 ng/mL in serum/saline	+	+	+	+	+	—	—

rMulti-CSF, recombinant multipotential colony-stimulating factor.

Assays performed using Limulus amebocyte lysate assay[15] and were performed on material remaining in bottles after completion of the injection schedule for mice injected with rMulti-CSF or serum/saline. The endotoxin standard was added to the same batch of mouse serum/saline used for injection; + = coagulated and ± = markedly increased viscosity. Mixture of rMulti-CSF with standard endotoxin did not inhibit the ability of endotoxin to be detected.

The cells were then centrifuged for 30 minutes at 1,200 g. The second interface contained 70% to 90% neutrophils, 5% to 10% eosinophils, and 10% to 30% mononuclear cells. Peritoneal cells were obtained as described above.

The phagocytosis assay used sheep erythrocytes coated with antibody (EA) as indicator cells and was carried out as previously described,[20] with minor modifications. The medium used throughout was RPMI 1640 containing 20 mmol/L of HEPES and 2% FCS. Erythrocytes were coated with antibody by incubating 5 × 10^7 cells in 1 mL with 10 μL (saturating amount) of ascites containing a mouse monoclonal IgG2b anti-E antibody[21] (Commonwealth Serum Laboratories, Parkville, Victoria, Australia) or a mouse monoclonal IgG2b anti-DNP (dinitrophenyl) antibody (K1), a gift from Dr C. Sanderson, N.I.M.R., London. Before incubation with the latter antibody, erythrocytes were coupled with TNP (trinitrophenyl) as described previously.[22] Erythrocytes were incubated with antibody for 40 minutes at 22 °C, after which the EA were washed three times to remove unbound antibody. Equal volumes (150 μL) of peritoneal cells or blood neutrophils (10^6/mL) and antibody-coated erythrocytes (5 × 10^7/mL) were then mixed in serology tubes and brought into contact by gentle centrifugation for 20 seconds at 100 g. After this, the mixtures were incubated in a water bath at 37 °C for 10 minutes (this short incubation time was necessary to avoid the lysis and disappearance of many phagocytosed erythrocytes). The incubation was stopped by adding 5 mL of ice-cold medium to the cells and washing them at 4 °C. From this stage on, the cells were kept on ice. The supernatants were then aspirated, and the cells were resuspended in 200 μL of ice-cold distilled water for 10 seconds to lyse extracellular erythrocytes. Isotonicity was quickly restored by adding 5 mL of ice-cold medium. The mixtures were then washed at 4 °C, the pellets were resuspended in a small volume of medium, and cytocentrifuge preparations were made. After the cells were fixed, they were stained with Giemsa. For each cell pool, incubations were performed in triplicate or quadruplicate, and at least 200 cells were counted per slide. Counts were performed on the percentage of phagocytosing cells and the total number of phagocytosed erythrocytes per 100 cells.

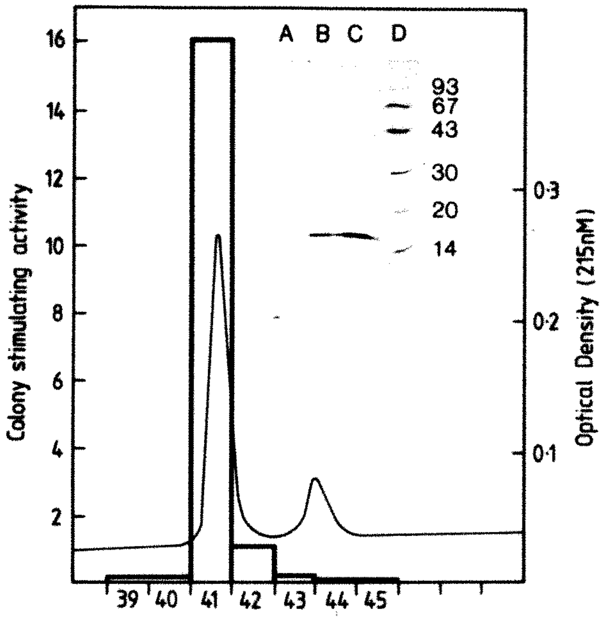

Fig 1. Final purification of bacterially synthesized recombinant multipotential colony-stimulating factor (rMulti-CSF) using reverse-phase high-performance liquid chromotography (HPLC). Assays for biological activity were performed using cultures of C57BL bone marrow cells. Insert shows the polyacrylamide gel electrophoresis of the peak fraction that exhibits a single silver-staining band of apparent mol wt 16,000. (A through C) increasing concentrations of peak fraction. (D) Mol wt markers: phosphorylase b, 93,000; bovine serum albumin 67,000; ovalbumin 43,000; carbonic anhydrase 30,000, soybean trypsin inhibitor 20,000; lysozyme 14,000.

RESULTS

When the recombinant Multi-CSF purified from *E coli* was subjected to final purification using HPLC reverse-phase fractionation, biological activity was coincident with a single ultraviolet (UV)-adsorbing peak (Fig 1). Material in the peak fraction ran as a single silver-staining band of mol wt 16,000 on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Based on granulocyte-macrophage colony formation in bone marrow assays and amino acid analysis of the peak fraction, the biological activity of the purified recombinant Multi-CSF was found to be 5 × 10^8 U per milligram. This material was diluted 1:500 in 10% mouse serum/saline after passage through a PD-10 column to remove residual acetonitrile. The volume of rMulti-CSF injected was 0.2 mL per injection and contained 102,000 U of rMulti-CSF (200 ng).

Toxicity studies on material injected. Assays for endotoxin content were performed on each batch of recombinant Multi-CSF and the carrier serum/saline both prior to and following each course of injection, sampling the material actually used for injection. No endotoxin was detected in any batch used and, as shown in the example in Table 1, the Limulus amebocyte lysate test used was able to detect 0.06 ng of endotoxin per milliliter, detection not being prevented by addition of mouse serum/saline or recombinant Multi-CSF. Despite the absence of detectable endotoxin, in some studies control mice were injected with mouse serum/saline to which 0.25 ng or 1.0 ng of endotoxin had been added per milliliter (that is up to 16 times the endotoxin level that might possibly have been present in the Multi-CSF preparations). In view of the essentially negative results obtained with these mice, only the data from mice injected with 1.0 ng of endotoxin per milliliter will be shown.

In preliminary studies, injection of mice with recombinant Multi-CSF still containing the acetonitrile in trifluoroacetic acid used for elution from the HPLC column was observed to lead to the development of lipid accumulation in the liver. Because of this, all material used in the studies to be described was processed through Sephadex G-25 M (PD-10) columns to remove the solvent, and no lipid accumulation was noted in the liver of mice injected with the processed material. As an additional control study, in four separate experiments acetonitrile in trifluoroacetic acid at the same concentration present in the Multi-CSF preparation prior to PD-10 processing was added to serum/saline. Injection of this material to mice induced lipid accumulation in the liver but failed to induce any of the hematopoietic changes to be described in mice injected with Multi-CSF (peritoneal cell changes, infiltration of cells in the liver, spleen size increase, changes in spleen cell content or progenitor cell levels).

Assays of rMulti-CSF levels achieved by injection. To determine the levels of rMulti-CSF achieved by a single IP injection of 102,000 U, groups of adult C57BL mice were injected, then serum was collected at intervals from 10 minutes to 6 hours. After killing at each timepoint, 2 mL of 10% FCS/saline was injected IP and, after abdominal massage, a sample of the fluid was withdrawn. For purposes of calculation, it was assumed that the resident volume of fluid in the peritoneal cavity was 0.2 mL. Assays for rMulti-CSF levels were performed on serial twofold dilutions of serum or harvested peritoneal fluid using agar cultures of 75,000 C57BL marrow cells. To verify that the CSF detected was indeed Multi-CSF, parallel assays were performed using agar cultures of 32D cells, responsive only to stimulation by Multi-CSF.[16] The data from the two sets of assays were in close agreement, and those from the bone marrow assays are shown in Fig 2, presented as the concentration of rMulti-CSF in BM U/mL of serum or per milliliter of the assumed resident volume of peritoneal fluid (0.2 mL). rMulti-CSF levels in the peritoneal cavity fell, with a half-life (t½) of ~20 min. Concentrations in excess of 50 U/mL (the concentration stimulating the formation of half-maximal numbers of colonies in an agar culture) were maintained for 4 hours. Serum levels of Multi-CSF rose sharply following injection and achieved peak levels between 0.5 and 1 hour following injection. Peak levels were ~6000 U/mL and thereafter levels fell again with a t½ of ~20 minutes. Serum levels above 50 U/mL were sustained for ~2.5 hours.

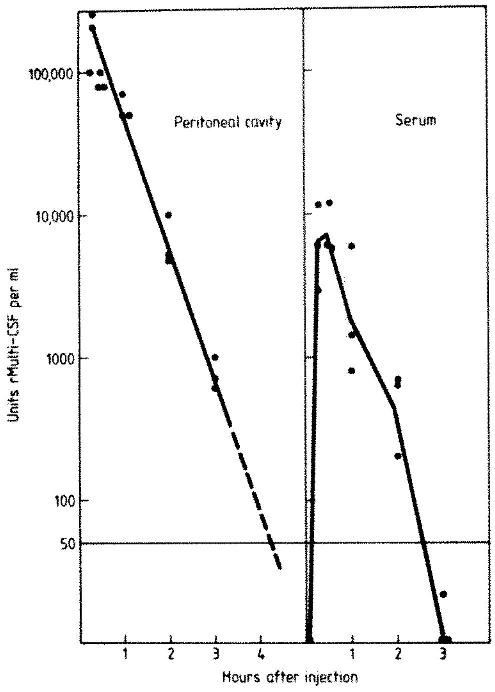

Fig 2. Levels of recombinant multipotentential colony-stimulating factor (rMulti-CSF) in the serum and peritoneal cavity in U/mL at intervals after a single intraperitoneal injection of 102,000 U of bacterially synthesized rMulti-CSF. Assays performed using serial dilutions of test material in cultures of 75,000 C57BL bone marrow cells. Each point represents an individual mouse.

It was concluded that each intraperitoneal injection achieved concentrations of rMulti-CSF that would be supramaximal in in vitro colony assays (ie, >400 U/mL) for 2 hours in the serum and 3 hours in the peritoneal cavity and significantly elevated levels (ie, >50 U/mL) for 2.5 hours in the serum and 4 hours in the peritoneal cavity.

White cell levels. As shown in Fig 3, C57BL mice injected three times daily with rMulti-CSF developed up to a tenfold rise in blood eosinophil levels as compared with control mice injected with serum/saline. Eosinophil levels rose progressively as injections were continued. Minor and less constant rises (twofold to threefold) were observed in polymorph and monocyte levels. No significant changes were observed in lymphocyte, reticulocyte, or hematocrit levels during or immediately after a 6-day course of injections. No mast cells, megakaryocytes, or nucleated red cells were observed in the peripheral blood of mice injected with rMulti-CSF.

Spleen changes. Spleens from C57BL mice injected for 6 days with rMulti-CSF showed a consistent weight increase of 50% (Table 2). Analysis of cytocentrifuge preparations of spleen cell suspensions (Table 2) showed a fourfold rise in the percentage of promyelocytes with primary granules and myelocytes and a twofold to threefold rise in blast cells, eosinophils, and nucleated red cells (the latter including recognizable erythroblasts), as compared to those of uninjected mice or control mice injected with serum/saline.

In histological sections of the spleens of mice injected with rMulti-CSF, no obvious changes were observed in lymphoid follicles or germinal centers. Similarly, there was no overt increase in the content of erythroid or granulocytic cells in the red pulp. However, counts of the numbers of the mature

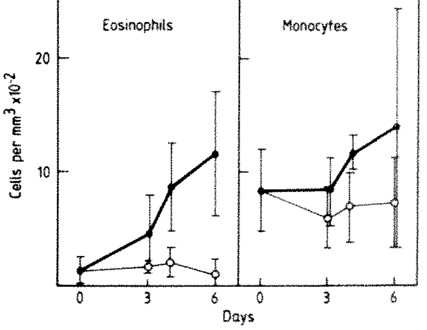

Fig 3. Changes in peripheral blood levels of WBCs in C57BL mice injected with recombinant multipotential colony-stimulating factor (rMulti-CSF) (heavy lines) and in control mice injected with serum/saline (light lines). Each point represents the mean value from 4 to 12 mice ± SD.

Table 2. Changes in Spleen Cell Populations in C57BL Mice Injected With rMulti-CSF

Group	Mean Spleen Weight (mg)	Percentage of Cells						
		Blasts	Promyelocytes and Myelocytes	Metamyelocytes and Neutrophils	Lymphocytes	Monocytes	Eosinophils	Nucleated RBCs
rMulti-CSF	160 ± 70	1.6 ± 1.4	2.8 ± 3.9	9.9 ± 7.3	68.0 ± 16.5	6.3 ± 2.1	1.3 ± 1.1	10.1 ± 5.9
Serum/saline	100 ± 40	0.6 ± 0.8	0.7 ± 1.2	9.3 ± 4.8	80.1 ± 7.7	4.5 ± 2.4	0.6 ± 0.9	4.2 ± 3.2
Uninjected	100 ± 40	0.7 ± 0.8	0.5 ± 0.7	8.9 ± 5.3	81.6 ± 6.6	5.1 ± 2.1	0.3 ± 0.7	2.9 ± 2.3

rMulti-CSF, recombinant multipotential colony-stimulating factor.

C57BL mice injected three times daily for 6 days and examined on day 7. Mean data for 12 mice per group ± SD.

megakaryocytes revealed a twofold to fourfold increase in mice injected for 6 days with rMulti-CSF (Table 3). More dramatic changes were observed in the mast cell content of the spleens of mice injected with rMulti-CSF. In control mice, small numbers of large, heavily granulated mast cells were observed (Fig 4). In the spleens of mice injected with rMulti-CSF, the number of such cells showed no change or a twofold to fourfold increase. However, the spleens of mice injected with rMulti-CSF also contained large numbers of small, incompletely granulated mast cells, which often occurred in clusters reminiscent of in vitro colonies (Fig 4) and were commonly located in the perifollicular sinus regions. The rise in the frequency of these small mast cells was only fivefold to 20-fold in C57BL mice; in C3H/HeJ and BALB/c mice, however, the rise was 100-fold (Table 3). Injection of endotoxin (1 ng/mL) failed to elicit these rises in mast cell numbers.

Spleens from C57BL mice injected for 6 days with rMulti-CSF showed a fivefold to eightfold increase in the frequency of granulocyte and/or macrophage and eosinophil progenitor cells as compared with those of uninjected mice or mice injected with serum/saline (Table 4). Analysis of these colonies revealed no significant differences between the groups in the relative frequency of different colony types. Changes of similar magnitude were noted in the spleens of C3H/HeJ and BALB/c mice following a 6-day injection course. Sequential studies indicated that the elevation in spleen progenitor cell levels in C57BL mice injected with rMulti-CSF was already present after 3 days of injections (rMulti-CSF mice: 44 ± 36 CFC/10^5 cells *v* 8 ± 6 CFC/10^5 cells for serum/saline-injected mice).

Similar changes were observed in levels of erythroid progenitor cells (CFU-E, BFU-E, and Mix-CFC). As shown in Table 5, mice injected for 6 days with rMulti-CSF showed a sixfold to 18-fold rise in CFU-E levels in the spleen and a twofold to tenfold fold rise in the frequency of BFU-E and Mix-CFC.

In three experiments using C57BL, BALB/c, and C3H/HeJ mice, the injection of endotoxin (1 ng/mL) for 6 days failed to elevate progenitor cell levels in the spleen above levels in uninjected mice.

Bone marrow changes. Total cell counts were slightly reduced in the femurs of C57BL mice injected with rMulti-CSF (Table 6). Slight but nonsignificant rises were observed

Table 3. Changes in Megakaryocyte and Mast Cell Numbers in the Spleen of Mice Injected With rMulti-CSF

Strain	Group	Comparative Megakaryocyte Nos. per Spleen	Comparative Mast Cell Nos. per Spleen	
			Large	Small
C57BL				
	rMulti-CSF	479 ± 260	4 ± 3	50 ± 33

	Uninjected	230 ± 54	19 ± 17	10 ± 9

rMulti-CSF, recombinant multipotential colony-stimulating factor.

Four mice per group were injected three times daily for 6 days and examined on day 7. Megakaryocyte counts were performed on sections of the entire spleen stained with hematoxylin-eosin. Mast cell counts were performed on sections of the spleen stained with Alcian blue-safronin.

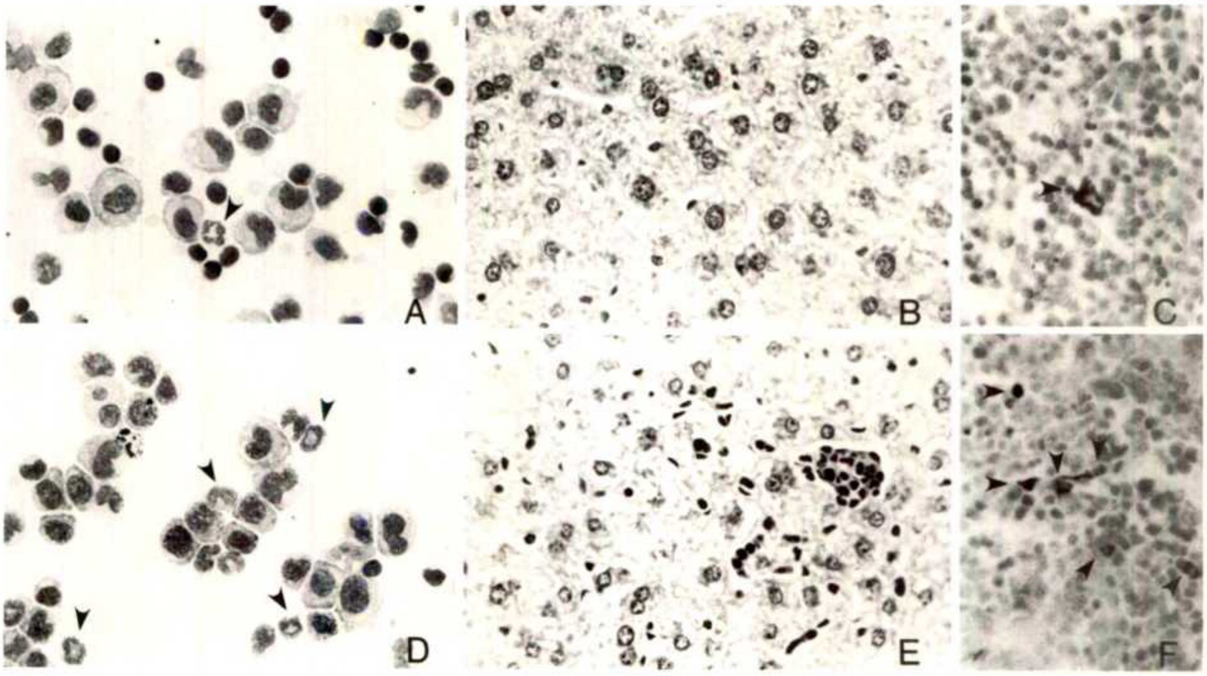

Fig 4. Comparison of mice injected for 6 days with recombinant multipotential colony-stimulating factor (rMulti-CSF) with control mice injected with serum/saline. (A) Control peritoneal cells with a single neutrophil (D). rMulti-CSF peritoneal cells showing increased proportions of macrophages and eosinophils (arrows). (B) Control liver and (E) rMulti-CSF liver showing focal and diffuse infiltration of hemopoietic cells. (C) Control spleen with a solitary large mast cell (arrow). (F) rMulti-CSF spleen showing part of a focus of small, incompletely granulated mast cells (arrows). May-Grunwald-Giemsa stain (A and D); hematoxylin and eosin stain (B and E); Alcian blue-safronin stain (C and F).

in the frequency of blast cells, differentiating granulocytes, and eosinophils. These rises were accompanied by a fall in the frequency of marrow lymphocytes. The frequency of nucleated erythroid cells was not elevated in marrow of mice injected with rMulti-CSF. No mast cells or basophils were observed in the marrow of rMulti-CSF-injected or control mice.

The frequency of granulocyte-macrophage, eosinophil, and erythroid progenitors was essentially similar in the rMulti-CSF-injected and control groups, and no differences were observed in the relative frequencies of colonies of these types (Tables 5 and 7). A similar lack of change in progenitor cell levels was observed in the mice injected for only 3 or 4 days with rMulti-CSF.

Table 4. Elevated Frequency of Progenitor Cells in the Spleens of C57BL Mice Injected With rMulti-CSF

Group	Nonerythroid Progenitors per 10^5 Cells	Percentage of Nonerythroid Colonies G	GM	M	Eosin
rMulti-CSF	48 ± 30	46	27	23	4
Serum/saline	9 ± 4	39	25	32	4
Uninjected	6 ± 7	20	20	60	0

rMulti-CSF, recombinant multipotential colony-stimulating factor; G, granulocytic; GM, granulocyte-macrophage; M, macrophage; Eosin, eosinophil.

Mice were injected three times daily for 6 days and analyzed on day 7. Mean data for 12 C57BL mice in each group ± SD. Replicate cultures of 50,000 spleen cells were stimulated by 3,200 U/mL GM-CSF. At 7 days, colony counts were performed, and colony morphology was determined from whole-culture preparations stained with Luxol Fast Blue-hematoxylin.

Liver changes. Livers of C57BL mice injected for 6 days with rMulti-CSF showed an increased cellular infiltration of two types: (a) a uniformly dispersed infiltration, and (b) in many mice, small focal aggregates of hematopoietic cells not associated with major blood vessels (in many mice) (Fig 4). As shown in Fig 5, counts on random high-power fields that avoided areas of focal infiltration showed an ~50% increase in nonparenchymatal cells per field as compared with those of control mice injected with serum/saline or serum/saline containing 1 ng/mL endotoxin or uninjected mice. The additional infiltrating cells were a mixture of granulocytes and monocytes with a prominent component of eosinophils; the cells in focal aggregates were of the same types. The infiltrating cells were at varying stages of maturation, but mitotic activity was not observed. Occasional megakaryocytes were observed in livers from rMulti-CSF-injected mice but not in control livers. No mast cells or nucleated erythroid cells were observed in any of the livers.

Because of the presence of focal collections of hematopoietic cells in the livers of C57BL mice injected with rMulti-CSF, the above data underestimate the actual levels of infiltrating cells in this strain.

Cellular infiltration was much less apparent in the livers of C3H/HeJ or BALB/c mice injected with rMulti-CSF, as

Table 5. Effect of rMulti-CSF on Frequency of Erythroid Progenitor Cells in Spleen and Bone Marrow

		Erythroid Progenitors per 10^5 Spleen Cells			Erythroid Progenitors per 10^5 Bone Marrow Cells

C57BL mice were injected three time daily for 6 days and then examined on day 7. Mean data for 12 mice per group ± SD.

confirmed by counts on random fields (nonparenchymatal cells per field: C3H/HeJ:rMulti-CSF 10 ± 1, serum/saline 8 ± 2, uninjected 8 ± 1; BALB/c rMulti-CSF 11 ± 1, serum/saline 9 ± 1, uninjected 8 ± 1).

Peritoneal population changes. The most prominent absolute change in cell populations observed in mice injected with rMulti-CSF was an increase in total cells in the peritoneal cavity. The increased cellularity was apparent to the naked eye as a milky opalescence of the harvested cell suspension. As shown in Fig 6, the changes induced by rMulti-CSF in C57BL mice were a sixfold rise in total macrophages, a 15-fold rise in eosinophils and a sevenfold rise in mature neutrophils. Total mast cell and lymphocyte numbers were not altered by rMulti-CSF injections, and no nucleated erythroid cells were observed in the peritoneal cell populations.

Table 7. Frequency of Progenitor Cells in the Bone Marrow of Mice Injected With rMulti-CSF

		Percentage of Colonies			
Group	Nonerythroid Progenitors per 10^5 Cells	G	GM	M	Eosin
rMulti-CSF	141 ± 50	33	40	27	0
Serum/saline	132 ± 44	24	31	45	0
Uninjected	146 ± 50	27	36	30	7

rMulti-CSF, recombinant multipotential colony-stimulating factor.

C57BL mice were injected three times daily for 6 days and then analyzed on day 7. Mean data for 12 mice per group ± SD in replicate cultures of 25,000 marrow cells stimulated by 3,200 U/mL GM-CSF. Colony counts were performed at day 7, and colony morphology was determined from whole-culture preparations stained with Luxol Fast Blue-hematoxylin.

Sequential observations indicated that no increase in peritoneal cell numbers had occurred 3 or 6 hours after a single injection of rMulti-CSF. Neither had the cellular composition of the peritoneal populations changed. The rises in peritoneal cell numbers were progressive during the 7-day observation period.

The additional macrophages appearing in the peritoneal cavity of rMulti-CSF-injected mice tended to be more baso-

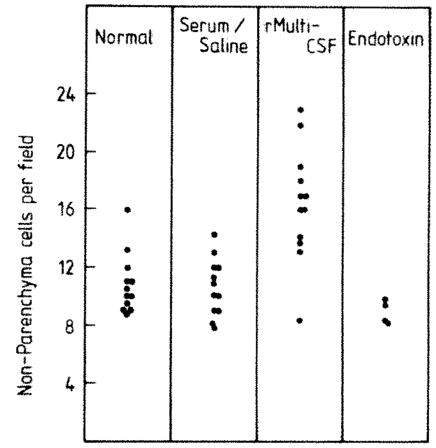

Fig 5. Rise in nonparenchymal cells (granulocytes, macrophages, and eosinophils) per high power field in sections of the liver of C57BL mice injected for 6 days with recombinant multipotential colony-stimulating factor (rMulti-CSF) as compared with the frequency of such cells in uninjected mice or control mice injected with serum/saline or serum/saline containing 1 ng/mL of endotoxin. Each point represents the mean data from six fields randomly selected from an individual liver section.

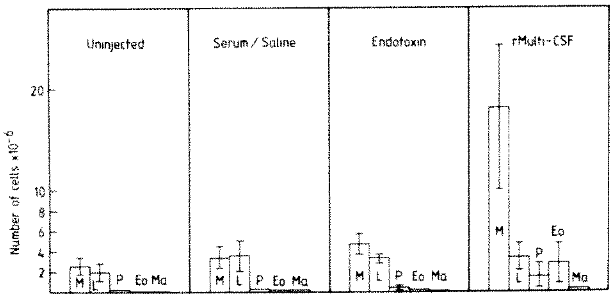

Fig 6. Total peritoneal cavity cells in C57BL mice injected for 6 days with recombinant multipotential colony-stimulating factor (rMulti-CSF) as compared with levels in uninjected mice or control mice injected with serum/saline or serum/saline containing 1 ng/mL of endotoxin; 12 mice per group. Mean values ± SD. M, macrophages; L, lymphocytes; P, polymorphs (neutrophils); Eo, eosinophils; Ma, mast cells.

philic and more vacuolated than were control peritoneal macrophages and occasionally were observed to have phagocytosed eosinophils. An increased level of mitotic activity was observed after 3 and 4 days of injection in peritoneal macrophages from mice injected with rMulti-CSF (mitoses per 10^3 cells: rMulti-CSF 7.4, serum/saline 0.9, uninjected 1.9); by day 7, however, the frequency of mitotic cells had fallen to control levels (mitoses per 10^3 cells: rMulti-CSF 1.2, serum/saline 1.2, uninjected <0.1).

Parallel studies using C3H/HeJ mice injected for 6 days also showed that rMulti-CSF induced major rises in macrophage, eosinophil, and neutrophil levels in the peritoneal cavity (Fig 7) although the absolute levels of these cells were lower than those observed in C57BL mice. Rises in peritoneal cell numbers in BALB/c mice were intermediate between those of C57BL and C3H/HeJ mice.

The injection of endotoxin (1 ng/mL) into mice of all three strains failed to elicit the large rises observed in mice injected with rMulti-CSF.

Changes in other organs. Histological sections of other organs from mice injected for 6 days with rMulti-CSF revealed no infiltration of mixed hematopoietic cells comparable with that observed in the liver. In the mesenteric lymph node, a 30-fold rise in C3H/HeJ mice and a 70-fold rise in BALB/c mice was observed in small, incompletely granulated mast cells in mice injected with rMulti-CSF as compared with control mice. No mast cell increase was observed in the mesenteric node of C57BL mice injected with rMulti-CSF. In the kidney, occasional small mast cells were observed in the outer cortex of mice injected with rMulti-CSF, but not in the cortexes of control mice. No mast cell infiltration was observed in the lung or the heart. In the small bowel, infiltration of additional small mast cells in the base and body of the villae was observed in C3H/HeJ and BALB/c mice injected with rMulti-CSF (threefold and 40-fold, respectively) but no infiltration was observed in C57BL mice. The thymus showed a small number of additional small mast cells in mice injected with rMulti-CSF.

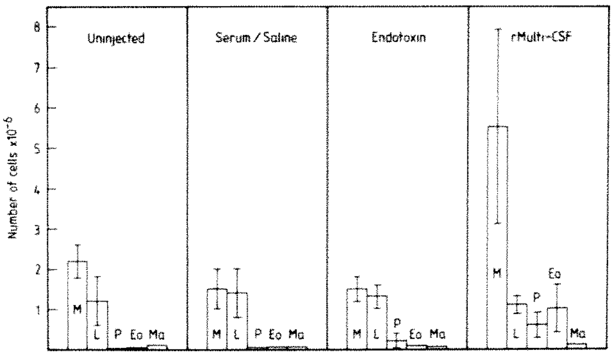

Fig 7. Total peritoneal cavity cells in C3H/HeJ mice injected for 6 days with recombinant multipotential colony-stimulating factor (rMulti-CSF) as compared with levels in uninjected mice or control mice injected with serum/saline or serum/saline containing 1 ng/mL of endotoxin; four mice per group. Mean values ± SD. M, macrophages; L, lymphocytes; P, polymorphs (neutrophils); Eo, eosinophils; Ma, mast cells.

In sections of flank skin, distant from the site of injections, a fivefold rise in small mast cells and a twofold increase in large mast cells was observed in C3H/HeJ and BALB/c mice injected for 6 days with rMulti-CSF as compared with control groups. Mast cells numbers were quite variable between individual mice within each group. No significant changes were observed in the skin content of mast cells in C57BL mice injected with rMulti-CSF.

Phagocytic activity of blood neutrophils and peritoneal macrophages. As shown in Table 8, a variable proportion of neutrophils from the peripheral blood of control mice exhibited phagocytic activity for antibody-coated erythrocytes, but cells from mice injected for 6 days with rMulti-CSF did not exhibit elevated phagocytic activity as assessed either by the percentage of phagocytic cells or the number of cells phagocytosed.

In contrast, macrophages from the peritoneal cavity of mice injected with rMulti-CSF exhibited a higher percentage of phagocytic cells and phagocytosed larger numbers of antibody-coated erythrocytes than did macrophages from control mice. Negligible phagocytosis was seen in the absence of opsonizing antibody. However, unlike the negative results with control injections using other parameters, the injection of serum/saline with or without added endotoxin increased the phagocytic activity of peritoneal macrophages. The effect of rMulti-CSF was distinguishable from that of endotoxin in the studies using endotoxin-hyporesponsive C3H/HeJ (Table 8). No differences were observed between the various groups in the phagocytic activity of peritoneal eosinophils, the percentage of phagocytic cells being low ($<10\%$) in all groups in which sufficient cells were available for scoring. No difference was observed between the phagocytic activity of peritoneal and blood neutrophils, and the injection of rMulti-CSF did not increase the activity of either population.

DISCUSSION

The IP injection of purified bacterially synthesized rMulti-CSF to normal adult mice produced detectable hematopoietic changes both at the site of injection and systemically. The nature of the responses observed and the cell types involved were in general agreement with expectations from

Table 8. Antibody-Dependent Phagocytosis by Peritoneal Macrophages and Blood Neutrophils From Mice Injected With rMulti-CSF

		C57BL		C57BL		C57BL		C3H/HeJ		BALB/c

In each experiment, pools of blood cells or peritoneal cells from four mice were used. Incubations to test for phagocytic activity were performed in triplicate or quadruplicate for each cell suspension. Data shown are percentages of phagocytic (Phag) cells as determined from counts on ≥600 cells and the total number of antibody-coated erythroid cells phagocytosed by 100 cells (EA/100 cells). In the third C57BL experiment, the erythrocytes were coupled with TNP and an anti-DNP antibody used. Groups are bracketed together where no statistically significant difference exists between the mean values by Tukey's method of least significant differences.

rMulti-CSF, recombinant multipotential colony-stimulating factor.

the actions of Multi-CSF as established from in vitro studies.[1-7]

Based on the assays of serum and peritoneal cavity fluid, a single injection of 102,000 U of rMulti-CSF only achieved significantly elevated (>50 U/mL) concentrations of Multi-CSF for 2½ hours in serum and 4 hours in the peritoneal cavity. With injections at intervals of 8 to 10 hours, this would have left the hematopoietic populations unstimulated for a major portion of each 24-hour period, and it is likely that the responses observed were below those that could have been achieved by using an indwelling osmotic pump or continuous intravenous infusion. However, it has been observed that occupancy of Multi-CSF receptors on bone marrow cells is rapid, essentially irreversible, and followed by a relatively slow reexpression of full membrane receptor numbers (N.A. Nicola, and L. Peterson, unpublished data, June 1985). Therefore it may be that the interrupted injection schedule used was less inefficient than might have been supposed.

In vitro, the effects of Multi-CSF on progenitor cell numbers are complex because of two opposing effects: (a) a decrease in progenitor cell numbers due to stimulation of these cells by Multi-CSF to form maturing progeny, and (b) an increased generation of progenitors by stimulation of stem cell cycling with progenitor cell formation.The net results of these opposing effects may well differ according to the Multi-CSF concentration used or to the cell population studied, eg, spleen *v* bone marrow. In the present in vivo experiments, no effects were observed on progenitor cell numbers or types in the marrow; in the spleen, however, twofold to tenfold rises were observed in granulocyte-macrophage, eosinophil, and erythroid progenitor cell levels with up to an 18-fold increase in CFU-E levels. In preliminary experiments using C57BL mice, the injection of rMulti-CSF for 6 days did not alter CFU-S levels in the marrow, but elevated the frequency of CFU-S fivefold in the spleen. These results are in general agreement with those of a similar study using bacterially synthesized Multi-CSF.[11] In can be concluded, therefore, that the regimen of injections used did not restrict the production of maturing cells by causing a depletion in progenitor cell numbers. On the contrary, it caused a significant rise in progenitor cells, at least in the spleen, an organ in the mouse noted for its ability to expand progenitor cell populations in situations involving increased hematopoiesis.[23-26]

Changes in maturing cell populations in the marrow and spleen reflected the above pattern. In the marrow, total cell numbers declined slightly, and no subset of cells showed a significant rise in frequency. In contrast, the spleen exhibited a consistent 50% weight increase and twofold to fourfold rises were observed in the percentages of immature granulocytes, eosinophils, nucleated RBCs, and megakaryocytes. The mast cell responses in the spleen to the injection of rMulti-CSF were quantitatively the largest, involving rises of tenfold to 100-fold in the population of small, incompletely granulated mast cells, these cells commonly developing in clusters resembling in vitro colonies. The mast cell response showed marked variation between the three mouse strains studied, being high in C3H/HeJ and BALB/c mice and much less prominent in C57BL mice, and were selective in that changes in the numbers of large mature mast cells were quantitatively much smaller (ranging from no change to a twofold to fourfold rise). The mast cell population changes in the spleen provided the most convincing single piece of evidence that injected rMulti-CSF was able to act systemically on hematopoietic target cells in normal hematopoietic organs.

The liver of the adult mouse normally contains no significant hematopoietic populations other than Kupffer cells, but the liver is an active site of hematopoiesis in fetal and neonatal life, and hematopoiesis can return to the liver in conditions of stress or damage to the bone marrow or spleen.[27] In this context, it is of interest that the liver was the only organ to display obvious infiltration by a mixed hematopoietic population in mice injected with rMulti-CSF. The infiltrating cells were at varying stages of maturation but exhibited no mitotic activity and presumably had seeded in the liver from the circulation.

The most striking overall population changes observed in mice injected IP with rMulti-CSF were in the peritoneal cavity itself. Here the population of macrophages rose sixfold, eosinophils rose 15-fold, and neutrophils rose sevenfold. Early in the injection period, increased mitotic activity was observable in the peritoneal macrophages from mice injected with rMulti-CSF; this declined, however as injections continued, either due to an inability of the cells to respond to further stimulation or, possibly, because migrating cells entering the cavity were nonresponsive. Mitotic activity in peritoneal macrophages could have accounted for some but probably not all of the rise in peritoneal macrophages and, since the increased neutrophils and eosinophils were exclusively postmitotic mature cells, it can be concluded that much of the increase in peritoneal cavity cellularity was owing to an influx of cells from the circulation. Human GM-CSF has been shown to inhibit neutrophil migration,[28] and a high local concentration of CSF might therefore encourage an accumulation of migratory cells. Because the spleen, bone marrow, and liver showed either no change or absolute rises in the populations of these cells, it is likely that the hematopoietic population rises in the peritoneal cavity and organs indicate a substantially increased production of mature cells during the 6-day injection period. Levels of circulating cells in the blood showed only moderate elevation, implying a more rapid transit of cells through the blood to seed in the peritoneal cavity and other tissues, an effect noted in early studies on mice injected with crude CSF-containing material.[29]

The macrophages from the peritoneal cavity of mice injected with rMulti-CSF exhibited increased phagocytic activity for antibody-coated erythrocytes and a morphology consistent with an activated state, eg, basophilia and vacuolation. Exposure of monocytes and macrophages in vitro to GM-CSF[30] or Multi-CSF[31] has been shown to increase their phagocytic activity, and a comparable stimulation by rMulti-CSF may have been the basis for the present in vivo effects. However, the effects could have been produced by some other biologically active mediator induced by rMulti-CSF or may even have been caused by the selective migration to the peritoneal cavity of a more active population of macrophages. Although exposure of neutrophils and eosinophils in vitro to some types of CSF induces increased functional activity,[32] no increased phagocytic activity by these cells was observed in the present experiments; it has yet to be established whether Multi-CSF can stimulate increased phagocytic activity by neutrophils and eosinophils in vitro.

In vivo studies of this type carry a known hazard that some or all of the changes observed may have been caused by contaminating endotoxin, the more so since the recombinant Multi-CSF used was synthesized by *E coli* and because endotoxin in high concentrations is capable of elevating progenitor cell levels in the spleen.[24,25] Throughout the present experiments, two types of control were used to exclude the possibility that the observed changes were due to endotoxin: (a) the use of a control group injected with at least 16-fold higher endotoxin concentrations than was detectable in the rMulti-CSF preparations, and (b) the use of endotoxin-hyporesponsive C3H/HeJ mice[33] to confirm all major observations. Several lines of evidence argue against the observed changes being due to endotoxin: (a) the recombinant Multi-CSF used was purified to homogeneity and contained no detectable endotoxin (<0.06 ng/mL); (b) injected endotoxin at higher concentrations (1 ng/mL) failed to produce the observed changes in the spleen, peritoneal or liver populations; and (c) similar responses to injected rMulti-CSF were observable in endotoxin-hyporesponsive C3H/HeJ mice.

Could the changes induced by the rMulti-CSF preparation have been caused by some other bacterial contaminant? There are several arguments against this possibility. First, amino acid sequence analysis of bacterially synthesized CSF purified by the present method shows only a single sequence with no evidence of contaminating polypeptides (R. Simpson, unpublished data, September 1985). Second, the crude commercial endotoxin preparation used was also of *E coli* origin and was more likely to contain such contaminants, yet failed to induce the changes produced by rMulti-CSF. Third, recombinant GM-CSF also synthesized by *E coli* and purified using the same general procedures produces a different response pattern when injected into adult mice, inducing no rises in immature mast cells and a fall in marrow progenitor cells (D. Metcalf, C.G. Begley, and G. R. Johnson, unpublished data, December 1985). Because the injected rMulti-CSF stimulated the same populations known to respond in vitro to purified native Multi-CSF, it seems reasonable to conclude that the observed in vivo effects were caused by the injected rMulti-CSF and not some hypothetical contaminant.

Although the actions of Multi-CSF in vitro have been established as direct effects on responding hematopoietic populations, there is no proof that the observed changes in vivo were caused by direct actions of the injected rMulti-CSF. However, injected ^{125}I-labeled rMulti-CSF has been shown to bind to marrow cells in vivo (N.A. Nicola, and D. Metcalf, unpublished data, July 1985), making it possible that the observed changes were direct effects of the injected rMulti-CSF. A formal possibility remains that the effects observed could have been initiated by rMulti-CSF but mediated by some other mechanism, eg, by the rMulti-CSF acting as an antigen or by the rMulti-CSF inducing the formation of some other biologically active molecule. However the presence of membrane receptors for Multi-CSF on the cell types responding in vivo (N.A. Nicola, and D. Metcalf, unpublished data, July 1985) makes it more likely that the action of injected rMulti-CSF was a direct one on responding cells.

Do the data establish Multi-CSF as a "normal regulator" in vivo? Multi-CSF is not detectable in normal serum[34,35] and, although activated normal T lymphocytes can synthesize high levels of Multi-CSF in vitro,[36,37] it remains unclear whether any Multi-CSF is synthesized in a normal spleen even though this organ presumably contains some activated T lymphocytes. From the marked rise observed in small mast cells in the spleen of mice injected with rMulti-CSF and their low numbers in the normal spleen, it seems doubtful whether significant concentrations of Multi-CSF are produced locally in a normal spleen. The present experiments suggest that Multi-CSF may not be an important regulator in steady-state conditions but might function as a highly effective regulator in states of T lymphocyte activation and consequent Multi-CSF synthesis.

The present studies using rMulti-CSF have provided a basis for the expectation that the CSFs will prove of value clinically in the stimulation of increased hematopoiesis when comparable human-active CSFs become available for testing. The marked strain differences observed in mice injected with rMulti-CSF predict that not all human subjects would respond in an identical manner to such injected CSF. Finally, the increased numbers and functional activation of cells at the site of injected CSFs raise the interesting possibility that the injection of CSF in sites of local infection or inflammation may be an effective method for enhancing host reponses to such local lesions.

ACKNOWLEDGMENT

The authors are indebted to Dr R.J. Simpson for performing the amino acid analysis of the rMulti-CSF and to Dr T. Brown (University of Melbourne) for assistance with the statistical analysis. The authors are particularly indebted to the excellent technical assistance of Cathy Quilici and to the technical assistance of Y. Wiluszynski, D. Vasiliadis, L. Oddo, and E. Viney.

Platelet von Willebrand Factor: An Important Determinant of the Bleeding Time in Type I von Willebrand's Disease

By Harvey R. Gralnick, Margaret E. Rick, Laurie P. McKeown, Sybil B. Williams, Robert I. Parker, Pascal Maisonneuve, Christine Jenneau, and Yvette Sultan

We studied 17 patients with moderate to mild type I von Willebrand's disease (vWd) and correlated the bleeding time with the plasma von Willebrand factor antigen (vWf Ag), the plasma vWf activity (ristocetin cofactor), the platelet vWf Ag, and the platelet vWf activity. We found an excellent correlation between the bleeding time and the platelet vWf activity and, to a lesser extent, between the bleeding time and the platelet vWf Ag. The length of the bleeding time was inversely proportional to the level of the platelet vWf ($P < .001$) or, to a lesser extent, the platelet vWf Ag ($P < .05$). The plasma vWf Ag and activity did not correlate significantly with the bleeding time. These studies indicate that the platelet vWf is one of the important bleeding time factors in type I vWd and that the platelet vWf plays an important role in the early steps of hemostasis.

THE CONGENITAL coagulation disorder, von Willebrand's disease (vWd), is characterized by a long bleeding time, low levels of factor VIII coagulant activity (VIII:C), von Willebrand factor antigen (vWf Ag), and ristocetin cofactor activity (vWf activity).[1,2] The most common form of vWd, ie, type I, is inherited in an autosomal manner and has a concordant reduction of all of the above mentioned activities.[2,3] However, the bleeding time is quite variable and often does not correlate well with the VIII: C, plasma vWf Ag and/or, in general, with the ristocetin cofactor activity (RCof).[1,4] This has led some investigators to suggest that a separate bleeding time factor exists that is deficient in vWd.[1,4] In an attempt to identify a factor that might be related to the bleeding time prolongation in vWd, we studied 21 patients with type I vWd (including four patients with severe disease and 17 patients with moderate to mild clinical symptoms) and correlated the bleeding time with the plasma and platelet vWf Ag and activity as measured by the RCof assay. In this study, we found that a prolonged bleeding time had an excellent correlation with a decreased level of platelet vWf activity and that a normal bleeding time correlated with normal platelet vWf activity. The plasma vWf Ag and vWf activity showed a poor correlation with the bleeding time values.

These studies indicate that an important determinant of bleeding time in type I vWd is the platelet vWf activity and suggest that it plays an important role in the initial phases of the formation of the hemostatic plug.

MATERIALS AND METHODS

Each patient gave informed consent for these studies. None of the patients were taking drugs known to affect factor VIII or vWf Ag or activity. Blood was obtained with a 19-gauge needle using a two-syringe technique. Plasma preparation and separation of platelets from whole blood were performed as previously described.[5,6] Platelets were isolated from whole blood anticoagulated with 10.9 mmol/L of sodium citrate, 1 mmol/L of EDTA by centrifugation on a discontinuous arabinogalactan (Stractan, St. Regis Co, Takoma, Wash) gradient (3 mL 20% of 5 mL 10% Stractan) as previously described.[5] In some experiments, 5 mmol/L of EDTA, 6 mmol/L *N*-ethylmaleimide, and 1 mmol/L of leupeptin were added to the anticoagulant used for the separation of plasma and platelets. Platelets were washed free of Stractan with 0.01 mol/L of Tris, 0.15 mol/L of NaCl, 0.003 mol/L of EDTA, and 0.5% serum bovine albumin (BSA), pH 6.8. After centrifugation at 1,500 g for 10 minutes, the platelet pellet was resuspended in 0.01 mol/L of Tris, 0.15 mol/L of NaCl, and 3% BSA, pH 7.35, incubated at 37 °C for 15 minutes, and then counted. The platelet count was adjusted to 10^6 platelets per microliter by the addition of resuspending buffer, and the platelets were lysed by the addition of 1/40 vol of 20% wt/wt Triton X-100. The platelets were then frozen at −70 °C; before analysis, they were thawed and spun at 10,000 g for 30 minutes at 4 °C. The supernatant was removed and used in the assays for vWf Ag and vWf activity.

Plasma VIII:C activity, plasma and platelet vWf Ag, and vWf activity were measured as previously described.[7] One unit of activity is defined as that found in 1 mL of pooled normal plasma. The bleeding time was performed on the patients' forearms using a standardized template method. Bleeding times and plasma and platelet vWf studies were performed on at least two separate occasions.

The multimeric structure of the plasma and platelet vWf were studied by glyoxal agarose gel electrophoresis modified from the technique originally described by Hoyer and Shainoff.[8] The major modifications were a gel thickness of 0.5 mm and a final sample size of 10 μL. Equal volumes of normal and patient plasma and platelet lysate were electrophoresed on the gel (regardless of the antigen content).

Three of the four patients with severe type I vWd had no family history of a bleeding disorder, whereas one patient had one family member (brother) who died of hemorrhage without a diagnosis ever being established. The other 17 patients with type I vWd had a personal history of bleeding and had at least one immediate family member with a similar bleeding history.

Classical correlation coefficients were determined on a Model 10 Hewlett-Packard programmable computer.

RESULTS

The four patients with severe homozygous or double heterozygous vWd were shown to have plasma and platelet vWf Ag and vWf activity of <0.03 U/mL (Figs 1 and 2) and bleeding times >30 minutes. In contrast, the 17 patients with moderate to mild type I vWd had bleeding times that ranged from 4 to 27 minutes and VIII:C levels that varied between 0.08 TO 0.75 U/mL. The plasma vWf Ag ranged between

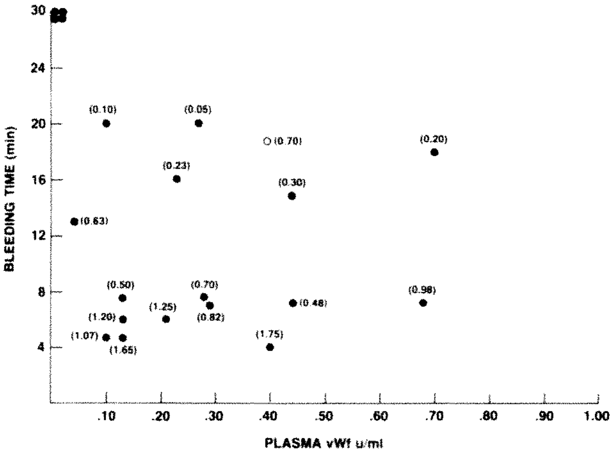

Fig 1. Comparison of the bleeding time with plasma von Willebrand factor (vWf) activity. The values in parentheses next to each of the closed circles represent the platelet vWf activity for that patient. The correlation of the plasma vWf activity and the bleeding time was very poor in that several patients had normal plasma vWf activity with long bleeding times and several patients had very low plasma vWf activity with normal bleeding times. The upper limit of normal for the bleeding time was 8 minutes; the lower limit of normal for the plasma vWf activity was 0.48 U/mL.

0.11 to 0.70 U/mL, and the plasma vWf activity varied between 0.05 to 0.70 U/mL (Table 1). Sixteen of the 17 patients had plasma vWf Ag below the normal range, and 15 patients had decreased plasma vWf activity. The platelet vWf Ag value varied between 0.22 to 1.30 U/10^9 platelets and the vWf activity varied between 0.05 to 1.75 U/10^9 platelets. Only 2 of the 17 patients had a decrease in platelet vWf Ag, whereas 5 patients had a decrease in their platelet vWf activity (Table 1).

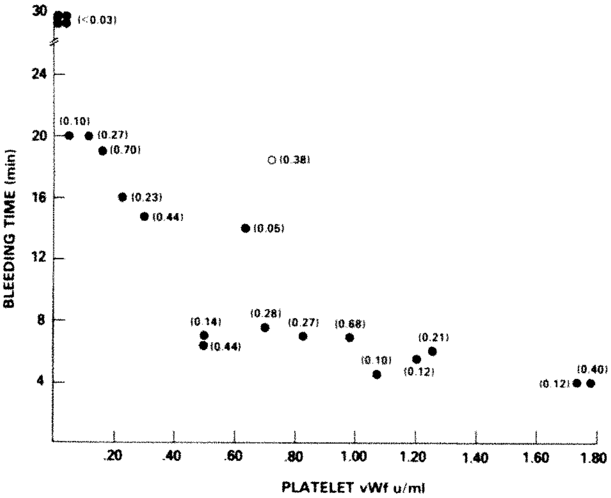

Fig 2. Correlation of the bleeding time and platelet von Willebrand factor (vWf) activity. All patients with moderate type I vWd who had low platelet vWf activity had prolonged bleeding times. Only two with normal platelet vWf activity had prolonged bleeding times. One of these patients (O) has an associated platelet aggregation defect; in the other plasma, vWf activity was 0.5 U/mL. The upper limit of normal for the bleeding time was 8 minutes; the lower limit of normal for the plasma vWf activity was 0.42 U/mL.

The correlation coefficients determined for the 17 patients with moderate to mild vWd are as follows. There was no correlation between the bleeding time and the VIII:C (data not shown), nor was there a correlation between the bleeding time and the plasma vWf Ag ($r = .2034$, $P > .10$) or vWf activity ($r = .1677$, $P > .10$) (Fig 1 and Table 1). In contrast, the relationship between the platelet vWf activity and the bleeding time revealed a remarkably good correlation ($r = .8055$, $P < .001$), whereas the correlation of the bleeding time with the platelet vWf Ag was significant but less than that observed with the platelet vWf activity ($r = .4895$, $P < 0.05$). The results of the duplicate analyses were within 1 to 2 minutes for the bleeding time and 10% to 16% for the plasma and platelet vWf studies.

The five patients who had decreased amounts of platelet vWf activity all had prolonged bleeding times, whereas 10 of the 12 patients with normal platelet vWf activity had normal bleeding times (Fig 2). The two patients who had normal levels of platelet vWf activity and prolonged bleeding times were somewhat unique. One of these patients (patient 4, Table 1) had a bleeding time of 17 minutes despite having a platelet vWf of 0.70 U/10^9 platelets. When he was given 1-deamino-8-D-arginine vasopressin (DDAVP), his bleeding time shortened to 10 minutes with a rise in his plasma VIII:C, vWf Ag, and RCof activity to normal levels. Later, he was restudied and was shown to have a platelet storage pool defect. The second patient had normal levels of vWf Ag and vWf activity in her platelets but had the most severe deficiency of plasma vWf (0.05 U/mL) and factor VIII:C. This woman had a bleeding time of 12.5 minutes, much shorter than would be expected from her plasma vWf levels. She had undergone five major surgical procedures (including a tonsillectomy, hysterectomy, and two spontaneous deliveries) with no excessive bleeding. Of the 17 patients with type I vWd listed in Table 1, patients 14, 15, and 16 are the father and two sons in one family, respectively; and patients 6 and 11 are the mother and son from another family.

Glyoxal agarose electrophoresis of the plasma and platelet vWf in the 17 type I patients revealed a multimeric pattern qualitatively indistinguishable from normal. There appeared to be a marked decrease in the plasma vWf Ag content in almost all patients and in the platelet vWf content of five patients (Fig 3). The presence of protease inhibitors in the anticoagulant did not modify the multimeric organization, vWf Ag levels, or vWf activity of the plasma or platelets.

DISCUSSION

In the first description of vWd, Willebrand noted that all of the affected family members had prolonged bleeding times; this became a prerequisite for the diagnosis of the disease which bears his name.[9] A 1968 study of 37 patients with vWd revealed that two patients had normal bleeding times, and a large study in 1977 revealed that 15 of 83 vWd patients with disease of moderate to clinical severity had normal bleeding times.[4,10] One study has suggested a good correlation between plasma vWf activity and the bleeding time,[11] whereas other investigators have found a poor correlation between the bleeding time and the plasma vWf Ag or

activity.[4,12] The inability to find a constant correlation between laboratory parameters and the bleeding time led to speculation concerning the factor(s) involved in the bleeding time in vWd.[1,4,12,13]

We studied 17 patients with heterozygous type I vWd and found an excellent correlation between the level of the platelet vWf activity and the bleeding time; the correlation between the platelet vWf Ag and the bleeding time was significant but not as strong as that seen with the platelet vWf activity. In contrast, the plasma levels of vWf Ag and/or activity did not correlate with the bleeding time. These studies indicate that the platelet vWf is a major factor in determining the bleeding time in the nontreated state in type I vWd. Our studies do not exclude an additive or independent role for plasma vWf but indicate that it appears to play a less significant role than that of the platelet vWf.

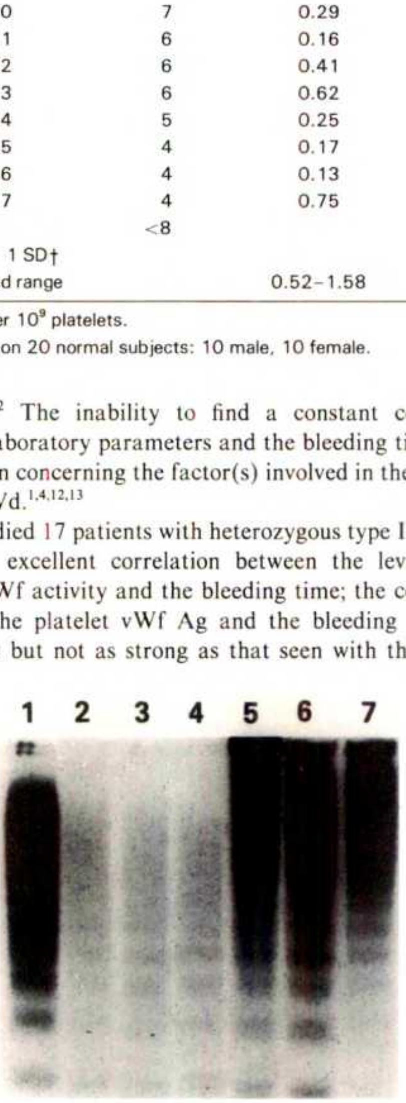

Fig 3. Agarose gel electrophoresis of the plasma and platelet vWf. Lane 1 is normal plasma; lanes 2, 3 and 4 are the plasma from a patient (patient 13, Table 1) collected in sodium citrate anticoagulant, in the same citrate anticoagulant with EDTA, and in sodium citrate, EDTA, and protease inhibitors, respectively. Lanes 5 and 6 are the patients' platelet vWf; blood in lane 5 was collected in sodium citrate and EDTA; in lane 6, it was collected in sodium citrate, EDTA, and protease inhibitors. Lane 7 shows normal platelet vWf for comparison.

Other studies reported subsets of patients with type I vWd who had normal platelet vWf Ag and in some cases vWf activity,[14,15] but no correlation was made between these values and any clinical parameter until recently. Mannucci and co-workers recently described six patients with type I vWd who had normal platelet vWf Ag and vWf activity. Two of these patients had normal resting bleeding times, and all six patients had a normal bleeding time after DDAVP infusions.[16] The patients with type I platelet low or platelet discordant vWd had prolonged bleeding times, and although the bleeding time shortened after DDAVP infusion, it did not become normal.[16] Ratnoff and Bennett reported that the bleeding time remained prolonged in three vWd patients in whom the VIII:C, vWf Ag, and plasma vWf activity rose to normal. It seems likely that in those patients the platelet vWf was still diminished and not affected by the pregnant state, by plasma product transfusion, or by the stress of hemorrhage.[12]

Our studies suggest that the platelet vWf is an important determinant in the bleeding time and that either the platelet membrane vWf or the vWf which is released after platelet stimulation acts as the initial bridge between platelets and the vessel wall, causing adhesion of these platelets to the vessel, or facilitates platelet–platelet interaction after adherence to the vessel wall.[17]

The findings of decreased levels of plasma vWf Ag and activity and normal or increased platelet vWf Ag and activity in some type I patients suggests that the genetic defect(s) that causes a decrease in the plasma vWf protein and its activities does not necessarily affect the platelet vWf and its activities. Further studies of type I vWd patients should include measurement of platelet vWf Ag and vWf activity. These studies focus on the importance of the platelet vWf activity in the determination of the bleeding time in vWd during a steady state. Further studies are necessary to identify the source and quantity of the vWf bound to subendothelium and the importance of the endothelial cell vWf and other cytoadhesive proteins in the determination of the bleeding time.

An Antigen Common to Chronic Lymphocytic and Hairy Cell Leukemia Cells Not Shared by Normal Lymphocytes or by Other Leukemic Cells

By Julia F. Agee, Fred A. Garver, and Guy B. Faguet

Rabbit xenoantisera and mouse monoclonal antibodies prepared against human chronic lymphocytic leukemia (CLL) B cells were found to react against a single polypeptide chain with a mol wt of 69 kd found on leukemic cells of all CLL (N = 40) and B type hairy cell leukemia (HCL) patients (N = 9) examined. This common CLL-associated antigen (cCLLa) was not detectable on circulating T or B lymphocytes, thymocytes, lymph node and splenic lymphocytes, or bone marrow leukocytes from normal persons. In addition, the cCLLa was not detectable on cultured T or B lymphoblastoid cell lines or on malignant cells from other forms of lymphocytic or myelocytic leukemia. Non-Hodgkin's lymphoma cells also failed to express the antigen. Autologous cultured lymphoblastoid cell lines were established from residual normal B cells from a CLL patient whose cells were used to generate one of the antisera. Absorption of the antibody with these cultured polyclonal B cells did not affect the anti-CLL activity, which suggests that the cCLLa is not HLA related. Unlike the T cell differentiation complex gp65-71, the cCLLa was not expressed on fetal or cord blood lymphocytes or on mitogen-stimulated normal lymphocytes and was distinct from the antigen recognized by the LEU-1 antibody in spite of their similar mol wt. The cCLLa was also determined to be unrelated to the human T cell leukemia lymphoma virus (HTLV-1). One of the monoclonal antibodies generated against the cCLLa was a complement binding IgG which exhibited highly selective cytotoxic activity against 100% of cells bearing the cCLLa. Such an antibody might prove clinically useful in early diagnosis and treatment of CLL and HCL.

DEFINING the expression of normal antigens on the surface of neoplastic hematopoietic cells has facilitated the elucidation of the cellular origin and differentiation pathways of these cells. Thus, leukemias and lymphomas, traditionally grouped according to histology, cell morphology, and cytochemistry, can now be subclassified based on their membrane markers.[1,2] Cells from patients with acute lymphoblastic leukemia (ALL), for example, exhibit T or B lymphocyte markers or lack both, the latter being associated with a better prognosis.[2-3] In contrast, malignant cells of most patients with chronic lymphocytic leukemia (CLL) express phenotypic markers characteristic of B lymphocytes.[4] The SIg of CLL cells with B phenotype has restricted heterogeneity as compared with that found on normal B cells, indicating a monoclonal origin of the leukemic cell.[5] Although the evidence supporting the existence of distinct tumor specific antigens in humans is circumstantial, efforts were made to identify surface antigens uniquely expressed on leukemic cells.[6-8] However, early reports of tumor-associated antigens on leukemic cells were met with skepticism in view of their lack of specificity. This and the observation that leukemia appears to be a consequence of a blocked differentiation rather than a loss of growth control[9,10] suggest that tumor-associated antigens are probably remnant "differentiation" antigens deleted during the differentiation process of normal cells.

In this communication, we report that CLL and hairy cell leukemia (HCL) share a common but unique antigen which appears distinct from differentiation antigens and is unrelated to antigens previously detected on leukemia or lymphoma cells, including the HTLV-1.

MATERIALS AND METHODS

Cells. Normal and CLL lymphocytes and blasts from leukemic patients were prepared from heparinized peripheral blood by Ficoll-Hypaque gradient modified to remove monocytes.[11] CLL cells were obtained from patients with B cell lymphoproliferations with circulating lymphocyte counts $>30{,}000/\mu L$. Promyelocytes were obtained from the buffy coat fraction after dextran sedimentation of venous blood from patients with acute promyelocytic leukemia (APrML). Thymic, splenic, lymph node, and bone marrow cells were teased from fresh biopsy specimens. Erythrocytes were removed from bone marrow samples by hypotonic lysis. B-enriched and T-enriched lymphocyte populations were separated according to the method of Weiner and colleagues.[12] B-enriched cells were in some instances prepared by the HEAC rosetting technique.[13] B-enriched and T-enriched lymphocyte preparations were consistently >80% and >90% phenotypically homogeneous, respectively. Myeloid and monocytoid cell contamination averaged <3%, respectively, as illustrated in Table 1. Lymphoid cell lines were established from peripheral blood lymphocytes of a CLL patient and of two patients with HCL as outlined by Moore.[14] Lymphoblastoid cell lines of B-cell (LS-1, MA-1, SA-1, KS-1, DBA-2, DBA-3, JY, B66, B110, B411, RPMI-1788, IM9, SB, and QIK) or T cell lineage (HSB, CEM, TAR, and MOLT-4), the pluripotent K562 cell line, and a fetal lymphoid cell line were cultured in appropriate media and stored in liquid nitrogen. Target cell preparations were characterized by cytomorphology and by surface marker phenotyping prior to assaying. Cell subset distribution in cell preparations is indicated in the text when appropriate.

Cell phenotyping. SIgs were determined by direct immunofluorescence[6] using fluorescein-conjugated antisera specific for IgM, IgG, IgA, and IgD heavy chains and for κ and λ light chains (Meloy Laboratories, Springfield, Va). Other surface determinants were assessed by indirect immunofluorescence assay (IFA) using appropriate monoclonal antibodies commercially available: (OKT series, Ortho Diagnostics, Raritan, NJ; LEU series, Becton Dickinson, Mountain View, Calif; and My$_4$, B$_2$, MO$_2$ and J-5, Coulter Immunology, Hialeah, Fla).

Anti-CLL antibodies. Xenogeneic antisera were produced in New Zealand white rabbits by biweekly intravenous (IV) injections

CLL, chronic lymphocytic leukemia; HTLV-1, human T cell leukemia lymphoma virus.

*Fresh cells were phenotyped by indirect immunofluorescence assay (IFA) using FITC-conjugated goat anti-mouse monoclonal antibodies (except for αCLL, which uses FITC-conjugated goat anti-rabbit antibody). SIg was assayed with FITC-conjugated goat anti-human antibody in a direct IFA.

†Cells were preincubated with αCLL prior to assaying in an indirect IFA using FITC-conjugated goat anti-mouse or goat anti-rabbit antibodies.

‡,§Mouse monoclonal antibodies against the HTLV-1 viral core proteins p19 and p24, respectively.

of 1 × 10^8 viable lymphocytes each from a single patient with B cell type CLL for 10 weeks with a final booster injection 2 weeks later. The antisera were heat-inactivated: 10 μL Trasylol (Aprotenin, Mobay Chemical Corp, NY) protease inhibitor was added, and anti-ABO antibodies were removed by absorption with 5 vol of AB erythrocytes. The sera were then individually absorbed with peripheral blood lymphocytes (PBL) (2.0 × 10^8/mL of antiserum) from each of three normal individuals who shared two or more HLA antigens with the antisera-generating CLL donor. The combined absorptions accounted for all of the HLA A, B, and C antigens detected on cells from each CLL donor. One absorbed antiserum (αCLL/αB) no longer reacted with T-enriched lymphocytes (92% E rosette-positive cells) but still reacted with CLL cells and with B-enriched lymphocytes (85% SIg-positive cells) from some normal donors. The latter reactivity was removed by absorption with either 3.0 × 10^8 B cells (87% SIg-positive cells) obtained by leukopheresis (cell centrifuge model 2997, IBM, Endicott, NY) of a normal subject whose B cells were reactive with antiserum αCLL/αB, or with 1.5 × 10^9 B cells from a lymphoblastoid culture line likewise reactive with antiserum αCLL/αB. After dialysis against 0.9% NaCl, the B cell-absorbed antiserum (αCLL) was centrifuged for 1 hour at 100,000 g to remove aggregated immunoglobulin. Alternatively, absorption of antiserum αCLL/αB with 0.5 × 10^9 CLL cells per milliliter from certain CLL patients generated an antiserum (αB) reactive against ~40% of B cells from 50% of normal individuals. Monoclonal mouse anti-human antibodies were also generated against CLL according to a modification (Faguet and Agee, manuscript in preparation) of the method of Kohler and Milstein.[15] Data of interest derived from one such antibody (CLL-1) are included in this report. All antibody preparations were used at titers sufficient to provide saturated binding conditions for all cells assayed. This was confirmed as follows: a first aliquot of CLL cells was incubated with αCLL or CLL-1 and a second aliquot of fresh CLL cells was exposed to supernatants of the first incubations. Both sets of cells assayed by IFA showed reactivity of comparable magnitude.

Immunofluorescence and cytotoxicity assays. Antibody reactivity against cells in suspension was determined by IFA[16] using fluorescein-labeled goat anti-rabbit IgG (Meloy) and goat anti-mouse IgG (Capel Laboratories, Cochranville, Pa) and by antibody-mediated cell lysis measured by ^{51}Cr-release cytotoxicity.[17] Antibodies were used in concentrations sufficient to achieve saturation binding. In each instance, nonimmune rabbit serum or irrelevant Ig were used as negative controls and to assess nonspecific binding and cytotoxicity. Appropriate commercially available monoclonal anti-T and anti-B cell antibodies were used as positive controls for both IFA and cytotoxicity studies of lymphoid target cells. Negative controls gave reactivity ranges of ≤ 4% and ≤ 10% for IFA and cytotoxicity, respectively. Positive controls gave reactivity ranges of 87% to 99% and 91% to 99% for normal B and T lymphocytes, respectively, and 64% to 100% for CLL cells regardless of assay used. Specific antimyeloid and antimonocytoid monoclonal antibodies were used mostly to ascertain the extent of nonlymphoid cell contamination of normal or CLL lymphocyte preparations.

Membrane preparation and partial purification. Membranes were prepared from leukemic cells obtained by leukopheresis of CLL patients with a WBC count of ≥ 300,000/μL according to a modified[18] published procedure.[19] Lyophilized samples from αCLL-IgG-Sepharose affinity column-purified membranes were dissolved in 10 nmol/L of phosphate buffer, pH 8.0, and applied to a 10-mL column (0.72 × 25 cm) of diethylaminoethanol (DEAE)-cellulose (DE-52, Whatman, Inc, Pierce Chemical Co, Rockford, Ill) equilibrated with the same buffer. The protein was eluted with a NaCl gradient made from 20 mL of .02 mol/L of NaCl and 20 mL of 2 mol/L of NaCl, followed by 10 mL of 3 mol/L of NaCl. One-milliliter fractions were collected, and the protein was located by measuring the absorption at 280 nm.

Gel electrophoresis. The homogeneity and mol wt of the antigen was assessed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) on 12% slab gels.[20] The antigen was dissolved in .0625 mol/L of Tris-HCL, pH 6.8, containing 0.005% bromophenol blue, 2% SDS, 2% mercaptoethanol, and 10% glycerol, and heated at 100°C for 3 to 5 minutes. Mercaptoethanol and heating treatment were omitted for nonreduced samples. The gels were fixed and stained with Coomassie blue or silver nitrate. The mol wt of protein bands was estimated by extrapolation from a standard curve (mol wt v mobility) using mol wt markers run simultaneously.

RESULTS

Antibody reactivity of antiserum αCLL/αB. Antiserum αCLL/αB was titered against CLL and normal B lymphocyte target cells as shown in Fig 1. Increasing the antiserum concentration-target cell ratio resulted in greater lysis of CLL cells than of B cells. At the maximum amount of antiserum added, 50 μL, lysis of B cells reached a plateau of 60%, whereas 20 μL of antiserum achieved 100% lysis of malignant CLL cells (cells bearing monoclonal SIg). These results suggested that the antiserum contained different antibodies reacting with both CLL cells and normal B cells,

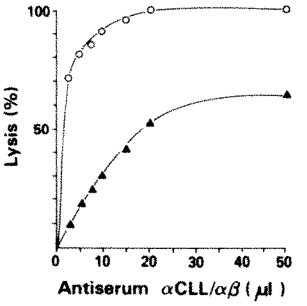

Fig 1. Titration of antiserum αCLL/αB by microcytoxicity assay with ^{51}Cr-labeled chronic lymphocytic leukemia (CLL) (o) or normal B (▲) target cells (5 × 10^4 per well). Percentage of lysis is expressed as a function of antiserum volume per well.

or that CLL cells exhibited either greater density of an antigen shared by normal B cells or greater affinity for a common antibody or were more susceptible to complement-mediated lysis than normal B cells were. In an effort to distinguish among the above possibilities, aliquots of antisera αCLL/αB were absorbed with B cells from seven normal subjects or with CLL cells from six patients and were assayed by cytotoxicity against ^{51}Cr-labeled normal B and CLL target cells (Table 2). As shown, enriched B cells (81% SIg positive) from certain normal subjects (Roc, Ta, Gre, Dor) reacted with the unabsorbed antiserum whereas others did not (Ger, Me). Absorption with B cells from any one reacting subject eliminated the antibody activity against B cells from that person and all previously reacting persons. Absorption with B cells from previously nonreacting persons (Ger, Me) failed to remove antibody activity to previously reacting B cells. However, both antisera remained markedly cytotoxic to CLL target cells regardless of whether they had been absorbed with reacting or nonreacting B cells. In contrast, absorption with CLL cells from some patients (Mil, Tay), abolished the antibody reactivity against both previously reacting normal B and CLL cells. Cells from other CLL patients (Bro, Wo, Lo, Tho) did not absorb out the antibody activity against previously reacting B cells, but did remove all antibody reactivity against CLL cells (eg, Lo). Furthermore, absorption of the antiserum with five times (2.5 × 10^8/0.1 mL) the number of normal B cells required to remove B cell antibody activity failed to remove cytotoxicity to CLL cells. These observations suggest distinct antigens on CLL and normal B cells rather than greater density on CLL cells of an antigen common to both. Thus, residual reactivity with Tay CLL target cells after absorption of antiserum αCLL/αB with CLL cells from Bro, Wo, Lo, and Tho is attributable to an antibody against the normal B cell antigen, which is absent on the absorbing CLL cells. Further studies conducted on B-enriched cells from normal donors (N = 25) and CLL cells from CLL patients (N = 26) indicate that this antibody identified a B cell subset (40%) found in ~50% of both normal subjects and CLL patients. Cell cultures were derived from peripheral blood of the CLL patient whose leukemic cells were originally used to generate antiserum αCLL/αB. Cells from one of these cultures expressed diverse SIgs (58% μ, 36% γ, 6% α, 63% κ and 31% λ), suggesting their polyclonal β cell origin. Although 82% of these cells reacted with the αB antiserum, only background reactivity (<4%) was seen with the αCLL antiserum (Table 3). As expected, absorption of the αCLL and αB antisera with these cells (4 × 10^7 cells/0.1 mL) did not affect the cytotoxicity of the αCLL for CLL target cells but abolished the lytic

CLL, chronic lymphocytic leukemia.

Normal B-enriched or CLL cells (0.5 × 10^8) were incubated with antiserum αCLL/αB (60 minutes at 15 °C) and centrifuged; cell-bound antibody was ascertained by ^{51}Cr-release antibody-dependent cytotoxicity asasy. Results are shown as percentage of lysis of triplicate determinations (SEM <2%). Values <10% are considered negative.

activity of the αB serum against both normal B cells and CLL cells initially reactive with the αB antiserum.

Specificity of the αCLL antibody. The specificity of the antibody preparation αCLL was further studied on a large panel of donors by both microcytotoxicity and immunofluorescence assays. As illustrated in Table 4, the αCLL antibody reacted with all 40 B-CLL patients tested with a range of lysis of 64% to 100% and a range of fluorescence of 73% to 100%. Included in this group were three patients with prolymphocytic leukemia (PLL). SeD, a cell line derived from a patient with CLL[21] also showed reactivity with the αCLL antibody. In addition, cells from nine patients with SIg-positive HCL were positive for the cCLLa, as were cell lines EH and HK derived from two HCL patients (Faguet and Agee, manuscript in preparation). To ascertain the identity of the antigenic determinant detected by the αCLL on CLL and HCL cells, the following studies were done: Saturating concentrations of αCLL were incubated with 10^6 B-CLL cells (93% monoclonal SIg positive) before and after absorption for 60 minutes at 15 °C with CLL or HCL cells or with T-enriched (96% OKT$_3$ positive) and B-enriched (83% SIg positive) lymphocytes from a normal donor at concentrations of 1.5×10^9/mL and assayed by IFA. CLL cell reactivity with unabsorbed antibody (92%) was completely abrogated by absorption with CLL (2%) or HCL cells (2%), but was unaffected by absorption with either normal T (93%) or B (92%) lymphocytes. Similar experiments using cells from two patients with HCL as target cells yielded comparable results. Neither CLL nor HCL cells with non-B phenotypes were available for testing.

Reactivity of the αCLL against normal and malignant cells was assayed by both ^{51}Cr-release cytotoxicity and immunofluorescence staining and showed similar results. Only immunofluorescence data are shown here.

CLL, chronic lymphocytic leukemia; cCLLa, common CLL-associated antigen; HCL, hairy cell leukemia; PBL, peripheral blood lymphocytes; PWM, pokeweed mitogen; PHA, phytohemagglutinin; CON-A, concanavalin-A; ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; AMMoL, acute myelomonoblastic leukemia; APrML, acute promyelocytic leukemia; CML, chronic myelogenous leukemia.

*Reactive cells are reported as percentage (SEM) of 600 cells counted for each assay except negative controls, which are reported as range.

PBL, T cells, and B cells from normal subjects showed only background reactvity with the αCLL antibody. Likewise, normal thymus, spleen, and lymph node lymphocytes were equally unreactive, as were bone marrow aspirates from four patients with anemia of chronic illness (Table 4). To evaluate whether the cCLLa represented a B cell differentiation antigen not expressed on mature B cells, the αCLL antiserum was reacted against cells likely to express such differentiation antigens, including cord blood lymphocytes, and 3-, 5-, and 7-day cultures of mitogen-stimulated normal blood lymphocytes.[22] As shown, lymphoid cells from all ten source categories and marrow interface cells failed to express the CLL antigen. The possible expression of the cCLLa on malignant cells of other types of leukemias was also investigated. Leukemias studied were: cALLa-positive and cALLa-negative acute lymphoblastic leukemia (ALL), acute myeloblastic leukemia (AML), acute myelomonoblastic leukemia (AMMoL), acute promyelocytic leukemia (AprML), and chronic myelocytic leukemia (CML) in blast crisis. As shown, none of the 32 leukemic patients examined expressed the cCLLa. Likewise, blood and lymph node lymphocytes from 14 patients with non-Hodgkin's lymphoma as well as lymph node lymphocytes and splenocytes from three patients with advanced Hodgkin's disease did not express the cCLLa antigen. Last, 14 lymphoblastoid B cell lines, 4 lymphoblastoid T cell lines, 1 fetal lymphoid cell line, and 1 pluripotent hematopoietic cell line also failed to express the cCLLa. Selective expression of the cCLLa described above has been confirmed by mouse monoclonal antibodies (Faguet and Agee, manuscript in preparation).

Isolation and partial characterization of the cCLLa. From 2.5×10^{10} CLL cells (B phenotype), 52 mg of membrane protein were recovered with a specific antigen activity of 0.1 U/μg as judged by cytotoxicity inhibition assay expressed as percentage of inhibition of 1 μg of αCLL IgG by 1 μg of membrane protein. Of this, 2.75 mg protein was recovered after passage through an αCLL-Sepharose affinity column. The immunoabsorbed-bound material had a specific antigen activity of 71 U/μg (710% cCLLa enrichment). Further fractionation by ion-exchange chromatography on a DEAE-cellulose column revealed three distinct peaks: Peak 1 had no activity at concentrations up to 150 μg per well; peak 2 consisted of 1.5 mg protein with cCLLa-activity of 156 U/μg protein (1,560-fold enrichment). Peak 3 consisted of a small component (0.8 mg protein) with low activity (2.7 U/μg protein). The specificity of peak 2 is shown by the fact that it did not inhibit lysis of B cells by the αB antiserum at concentrations up to 1,000 times that required for complete inhibition of αCLL-induced lysis of CLL cells. SDS-PAGE gels of peak 2 revealed a major band with an estimated mol wt of 69 kd both in the presence or absence of β-mercaptoethanol and heating (Fig 2). Two experiments served as controls: (a) Using the above procedure, B cell membranes prepared from 2.5×10^{10} B lymphocytes were applied to an αCLL-IgG-Sepharose affinity column; (b) an equivalent CLL membrane preparation was applied to an antihemoglobin A-IgG-Sepharose column equal in size to the αCLL-IgG-Sepharose affinity column. The immunoabsorbed material recovered from either column (0.56 mg and 0.84 mg of protein, respectively) showed no cCLLa activity at concentrations up to 150 μg of protein per well. In addition, further fractionation of these materials on a DEAE-cellulose column revealed only one peak (peak 1) with no cCLLa reactivity.

Further characterization of the cCLLa by monoclonal antibodies. The identity of the cCLLa was further ascertained as follows: Aliquots of 10^6 B-CLL cells enriched normal T and B lymphocytes were either preincubated with αCLL or not prior to exposure to a panel of monoclonal antibodies. Fresh cells were phenotyped as described in the Materials and Methods section. Cells preincubated with αCLL were assayed by indirect IFA using fluoresceinated goat anti-mouse or goat anti-rabbit antibodies to monitor mouse monoclonal and rabbit xenogeneic antibody binding, respectively. As shown in Table 1, the phenotype of fresh CLL cells and of fresh enriched circulating normal T and B lymphocytes demonstrated homogeneity of lineage. Fresh cells from each subset exhibited only background reactivity when exposed to J-5 and HTLV-1 antibodies (a generous gift from Dr D. Bolognesi, Duke University, Durham, NC). As expected, the LEU-1 antibody reacted with 88.3% of fresh CLL cells and with 92% of fresh T cells and showed background reactivity with fresh B cells. In contrast, the CLL-1 and αCLL antibodies reacted with 85.1% and 82.5%, respectively, of fresh CLL cells but did not react with either fresh normal T or B lymphocytes. The reactivity of LEU-1 with target CLL cells (88.3%) and with normal T lymphocytes (92%) was not altered by preincubation with αCLL (83.9% and 95.3%, respectively). In contrast, CLL-1 reactivity with target CLL cells (85.1%) was completely abrogated (2.9%) by preincubation with αCLL. That competitive binding to the target antigen by αCLL accounts for the abrogation of CLL-1 reactivity is supported by the use of goat anti-rabbit second antibody. Moreover, experiments in which preincubation of the CLL-1 with purified cCLLa completely abrogated its reactivity with target CLL cells demonstrate that the target antigen CLL-1 is indeed cCLLa (manuscript in preparation). Using a large panel of normal and neoplastic cells, CLL-1 reactivity has been demonstrated to parallel that of αCLL (Faguet and Agee, manuscript in preparation). As expected from their respective specificities for antigens other than the cCLLa, reactivity of the other antibodies of the panel was not altered by preincubation with αCLL and is shown in Table 1 as controls. The above observations strongly suggest nonidentity between the cCLLa and LEU-1 antigens and clearly demonstrate that the cCLLa is the common antigenic determinant for both CLL-1 and αCLL.

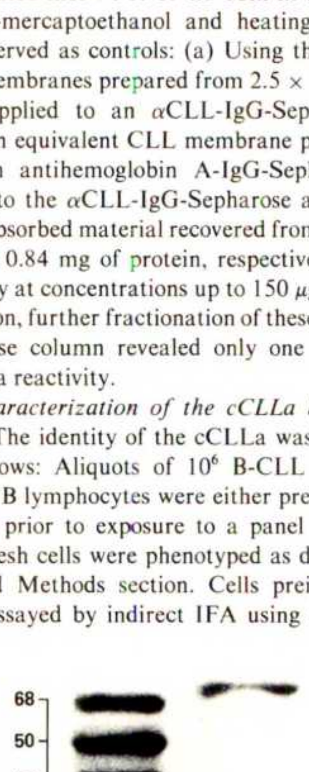

Fig 2. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of diethylaminoethanol (DEAE)-cellulose column peak 2 under reducing conditions (right lane). Mol wt markers (left lane) include: bovine albumin; IgG H-chain; ovalbumin; IgG L-chain; β-lactoglobulin; and lysozyme. Marker weights ($\times 10^{-3}$ daltons) are indicated.

DISCUSSION

The purpose of the present study was to explore the possible existence of distinct antigenic markers on CLL cells. Sequential absorption of the initial CLL antiserum with AB erythrocytes and HLA-matched peripheral blood lymphocytes resulted in a serum devoid of antibody activity against RBCs and T cells but retaining cytotoxicity against CLL cells and, to a lesser extent, B cells. Differential absorption with a panel of normal enriched B cells or CLL cells of B lineage suggested that the antiserum contained antibodies to an antigen found on 20% to 70% of B cells from ~50% of normal subjects and B-CLL patients and also antibodies against an antigen present on CLL cells but not on normal B lymphocytes. The different susceptibility of the two cell populations to antiserum αCLL/αB is attributed to two distinct antigens rather than to a different density of the same antigen on the two cell populations. This view is supported by the following observations: (a) distinct reactivity patterns after selective absorption with normal B or CLL cells; (b) persistence of anti-CLL activity after absorption with fivefold excess of B lymphocytes bearing free B antigen; (c) failure of autologous normal B lymphocytes to absorb anti-CLL activity, and (d) absence of cCLLa in normal B membrane preparations as demonstrated by chromatography studies and binding blocking experiments.

The cCLLa was expressed on most cells from all CLL patients studied but not on peripheral blood lymphocytes, enriched T and B cells from normal subjects, lymphocytes isolated from the thymus and spleen, or on other hematopoietic cells. However, these findings do not rule out the possibility that the antigen may be expressed by a minor subset of normal lymphocytes most susceptible to neoplastic transformation or that it is only transiently expressed early during differentiation, at a time when lymphocytes may be particularly susceptible to transformation and maturation arrest. This is consistent with the findings that CLL cells appear to be arrested in differentiation at an intermediate step between the pre-B and mature B lymphocyte stages.[23] The cCLLa was not detected on adult or fetal lymphoid cells or on cultured lymphoblastoid cell lines, in contrast to other xenoantisera generated against CLL.[6,22] In addition, retention of anti-CLL reactivity after absorption of αCLL with autologous residual normal B lymphocytes (fully histocompatible with respect to the normal antigens on the patient's leukemic cells) provides additional experimental evidence that CLL B cells express an antigen not detectable on autologous mature normal B cells. Unlike known differentiation antigens, this antigen was likewise not expressed on cord blood lymphocytes or during in vitro transformation of T and B lymphocytes using appropriate mitogens. This, and the fact that the cCLLa and LEU-1 are antigenically distinct, suggest that unlike the T cell differentiation antigen complex gp 65–71,[24-26] the 69-kd mol wt cCLLa may be more a reflection of the disease than a normal marker of lymphocyte differentiation unless the event occurs early at a stem-cell level. This is unlikely, however, because lymphoblasts from childhood and adult ALL failed to express the cCLLa. Moreover, because of the apparent common cell origin of B lymphocytes and myeloid cells in CML as judged by cytogenetics and enzyme markers,[27] some myeloid cells would be expected to express the cCLLa. Although such a predicted reactivity pattern has been observed with certain reported xenogeneic anti-CLL antisera that reacted with CML and AML cells,[12,13] none of the relatively few (N = 18) myeloid leukemias studied thus far expressed the cCLLa, nor did K562 cells, a pluripotent cell line derived from a patient with CMLBC.[28] The observation that lymphoma cells failed to express the cCLLa was unexpected, given the biologic and phenotypic similarities between these tissues and CLL. However, the number of cases studied thus far is small and both Hodgkin's tissues and non-Hodgkin's PBL are expected to have low if any cCLLa reactivity. Thus, recognition of a small subset of lymphoma patients with a cCLLa-positive clone requires further accrual of cases to our studies.

The clear demonstration of the cCLLa on malignant cells from nine patients with B-type HCL and three patients with PLL supports the view that CLL, PLL, and HCL are intermediary forms of lineage-related disorders[4] and suggests a common etiology for cCLLa-positive CLL, PLL, and HCL. In studies similar to those shown in Table 1, it was demonstrated that cCLLa is distinct from the HCL antigen recognized by monoclonal anti-HCL antibodies αHC1 and αHC2[29] (a gift from Dr D. Posnett, Rockefeller University, NY). Other monoclonal antibodies have been developed against normal and malignant T and B lymphocytes.[29-33] However, these antibodies also react with surface determinants shared by malignant and normal lymphoid cells, contrary to the restricted expression of the cCLLa recognized by αCLL and CLL-1 antibodies. The presence of HTLV-1 on CLL cells and its potential relationship to cCLLa were studied by binding and by cross-competition binding, respectively, using specific monoclonal antibodies against the major core proteins P19[34] and P24[35] and αCLL as blocking antibody in an IFA. Similar results were obtained using HCL cells as target cells (not shown). These findings and the observations that: (a) primary and cultured tumor cells of HTLV-1 positive malignancies are mature T cells[36,37]; (b) human cord blood exposed to HTLV-1 isolates infect T lymphocytes[38]; and (c) HTLV-1 sequences were absent in autologous B cells of patients whose neoplastic T cells contained HTLV-1 proviral sequences,[39] suggest that cCLLa-positive CLL, PLL, and HCL are not etiologically related to HTLV-1–induced T cell malignancies. However, our studies do not exclude an etiologic role for other retroviruses in B-lymphoid malignancies.

Monoclonal antibodies specific for the cCLLa and B cell lines expressing this antigen may be of clinical value: Detection of the cCLLa facilitates the diagnosis of a malignant lymphoid clone (manuscript in preparation) in a preclinical and potentially eradicable phase of its development. In addition, cCLLa-positive cell lines can be used to develop xenogeneic transplantation models (Faguet and Agee, manuscript in preparation) to ascertain the potential in vivo usefulness of cytolytic anti-CLL monoclonal antibodies and of their cytotoxic conjugates as immunotherapeutic agents.

ACKNOWLEDGMENT

Dr F. Garver advised J.F.A. for some of the studies. The authors thank Mrs M.A. Jones and Mrs S. Bright for typing this manuscript.

Nonrandom Involvement of the 12p12 Breakpoint in Chromosome Abnormalities of Childhood Acute Lymphoblastic Leukemia

By Susana C. Raimondi, Dorothy L. Williams, Thomas Callihan, Stephen Peiper, Gaston K. Rivera, and Sharon B. Murphy

We studied the presenting clinical and biologic features of 23 children with acute lymphoblastic leukemia (ALL) whose leukemic marrow karyotypes contained abnormalities involving the short arm of chromosome 12. Nineteen of the abnormalities were assigned to the 12p12 breakpoint. The median age of the children was 5 years (range 2 to 13 years) and their initial leukocyte counts ranged from 1,800 to 424,000/μL (median 30,000/μL). Twenty-one patients (91%) had common phenotype ALL (CALLA+, HLA-DR+), including three cases with a pre-B cell phenotype (CIg+). The remaining two cases were T cell in origin. The French-American-British (FAB) morphologic type of lymphoblastic leukemia was L1 in all cases but one. With a median follow-up of 11 months, four patients have relapsed and another failed induction therapy. The modal chromosome number in all cases was <50. Three distinct cytogenetic patterns, with apparently similar clinical manifestations, were noted: terminal deletions of chromosome 12 in 10 cases, apparently balanced reciprocal translocations in 6, and unbalanced translocations in 7. All translocations were between the 12p arm and different donor chromosomes except for chromosomes 7, 9, and 17, which participated twice. Only two patients had identical translocations: t(7;12)(q11;p12). This unusual variation in donor chromosomes and breakpoints suggests that translocations involving the 12p are specific with respect to only one member of the translocation pair, namely chromosome 12. The relatively high frequency of the 12p abnormalities in this study (10% of all completely banded cases seen over a 35-month period) warrants further investigation.

© 1986 by Grune & Stratton, Inc.

SINCE THE THIRD International Workshop on Chromosomes in Leukemia, 1980 (TIWCL), chromosome findings have been recognized as an important independent prognostic factor in ALL.[1] Despite difficulty in obtaining banded chromosomes, several independent groups have reported data similar to the findings of the workshop for both adults and children.[1-4] Previously, we confirmed the prognostic importance of chromosome number (ploidy groups) in 136 consecutively studied children with ALL.[5] That study demonstrated superior treatment responses for children with >50 chromosomes and poorer outcomes in children with pseudodiploid karyotypes, regardless of other risk factors. In addition, data published by the TIWCL,[1] Bloomfield and co-workers,[3] and Williams and co-workers[6] have indicated that translocations generally confer a poor prognosis in ALL. As a result of these findings, increased attention has been paid to the role of genetic rearrangements in the pathogenesis and clinical course of ALL.

The TIWCL also reviewed the characteristics and clinical correlations of nonrandom structural chromosomal abnormalities including t(4;11), t(8;14), t(9;22), 14q+ and 6q−. Williams and co-workers[7] have described two additional nonrandom translocations, the t(1;19) specific for pre-B ALL and the t(11;14) specific for the E+ subset of T cell ALL, as well as the 12p12 abnormality found primarily in association with the common ALL immunophenotype. We present here additional cytogenetic data on the frequency and various forms of the 12p abnormalities (primarily at breakpoint 12) in 23 cases of childhood ALL, together with the clinical and biologic correlates of these changes. Previously reported for individual cases[2,8,9,10] and proposed as a distinct cytogenetic subgroup,[7] 12p abnormalities emerge as one of the most frequent abnormalities encountered in our cytogenetic studies of childhood ALL. The 12p12 breakpoint is of particular interest because of its recent association with the human cellular homolog of the Kirsten sarcoma gene (K-*ras* 2).[11,12]

MATERIALS AND METHODS

Patients

The study group consisted of 23 children with newly diagnosed ALL who were admitted to St Jude Children's Research Hospital between November 1981 and December 1984. Three patients (nos. 5, 16, and 17) were also studied at relapse. Each child received modern multidrug systemic therapy and central nervous system (CNS) prophylaxis.[5,13]

Morphologic and Cytochemical Studies

Following informed consent, bone marrow aspirates obtained from the iliac crest were stained with Wright's stain and examined for cell morphology and differential counts. Morphologic classification followed criteria of the French-American-British (FAB) system.[14] The cytochemical stains used in light microscopic examinations included: myeloperoxidase, Sudan black B, periodic acid-Schiff (PAS), and α-naphthyl butyrate esterase (ANBE).[15]

Immunophenotyping

All patients were tested for their blast cell phenotype before treatment with use of standard methods for detection of surface and cytoplasmic markers characteristic of the lymphoid lineage and degree of differentiation.[16] Bone marrow aspirates were collected in heparin, and the mononuclear cells were separated on a Ficoll-

*Most consistent additional abnormality.

†Indicates the cases that had the 12p breakpoint not assigned to 12p12.

Hypaque gradient. Only samples containing >50% blasts were studied.

Cytogenetic Studies

Bone marrow samples from 21 patients and peripheral blood for 24-hour cultures in two patients (patients 1 and 18) were obtained at the time of diagnosis and processed according to the method of Williams and co-workers,[17] which incorporates numerous alterations of standard techniques. In brief, ~0.1–0.2 mL of heparinized bone marrow were collected in tubes containing 8 mL of RPMI 1640 with L-glutamine, antibiotics, and 30% fetal calf serum (FCS). The bone marrow cells were processed immediately following a 25-minute incubation in Colcemid (final concentration 0.06 μg/mL). Cells were rinsed twice in Hanks' balanced salt solution (HBSS). They were then exposed to hypotonic treatment (KCL 0.075 mol/L), for a total of 32 minutes at room temperature, including periods of mixing, standing, and centrifugation. The cells were then fixed in methanol-acetic acid (3:1, vol/vol) for 15 minutes. Slides were prepared using a flaming technique. The 24-hour unstimulated peripheral blood cultures were processed as described for bone marrow. Slides were allowed to age for 0 to 7 days. Metaphase preparations were G-banded by a modification of the trypsin method of Seabright[18] and chromosomes were identified and assigned according to the International System of Human Cytogenetics Nomenclature.[19]

RESULTS

Clinical and Biologic Characteristics

The presenting clinical features of the 23 children with an abnormality of the p arm of chromosome 12 are summarized in Table 1 according to the karyotypic complexity of each case as follows: terminal deletion (group I), apparently balanced reciprocal translocation (group II), and unbalanced translocation (group III) of known or unknown origin. There was no obvious pattern of clinical characteristics distinguishing these subsets of patients from the entire group seen during the same 35-month period. Leukocyte counts ranged from 1,800 to 424,000/μL (median, 30,000/μL), and ages ranged from 2 to 13 years (median 5). The ratio of males to females was 14:9. Patients 13, 14, and 20 had initial CNS involvement, but a mediastinal mass was not present in any of the subjects. With a median follow-up of 11 months (range 2 to 35 months), four patients (nos. 5, 14, 16 and 17) have relapsed, and another patient (no. 24) failed induction therapy.

The morphologic type of lymphoblastic leukemia was L1 in all cases except number 2, which was classified as L2. None of these patients' blast cells reacted with myeloperoxidase or Sudan black B, but PAS reactivity was noted in three cases (nos. 1, 2, and 5). Ten of the 24 marrow specimens were stained for ANBE, with occasional positive granules seen in three cases (nos. 14, 16, and 23).

Immunophenotypic analysis with a large panel of monoclonal antibodies disclosed CALLA+, HLA-DR+ blast cells in 21 (92%) of the 23 cases, consistent with differentiation in the B cell pathway.[20] Cytoplasmic immunoglobulin was present in three of the cases, indicative of a pre-B cell type. Two of the 25 patients had membrane markers denoting a T lymphocyte lineage. Blast cells from patient 2 were positive for the pan T cell antigens T9, T10, T6, and T4 corresponding with early to midthymocyte stages, whereas those from patient 21 had an early thymocyte phenotype as indicated by positivity for the T9 and T10 antigens.

Cytogenetic Features

The frequency of 12p abnormalities was ~10%, or 23 of 241 patients with completely banded chromosomes who were seen over a 35-month period. The cytogenetic findings are presented in detail in Table 1 and illustrated in Figs 1 through 3. In the individual cases, the 12p abnormality was found in 24% to 100% of all completely analyzed metaphases. However, such changes were also observed in metaphases that were not suitable for complete analysis, indicating that some cases were under-represented in this study. The majority of cases had 46 chromosomes, with a lower modal number in only two instances and hyperdiploidy (47 to 49) in six.

Group I (terminal deletion). Patients 1 through 8 (Table 1) had a terminal deletion of the p arm of chromosome 12 at band 12; examples are illustrated in Fig 1A through D. Three of these cases had the del(12)(p12) as their sole abnormality. The other five cases contained additional chromosome abnormalities that were either structural or numerical but apparently did not involve translocations; an exception was noted for patient 7, who had a derivative chromosome 16

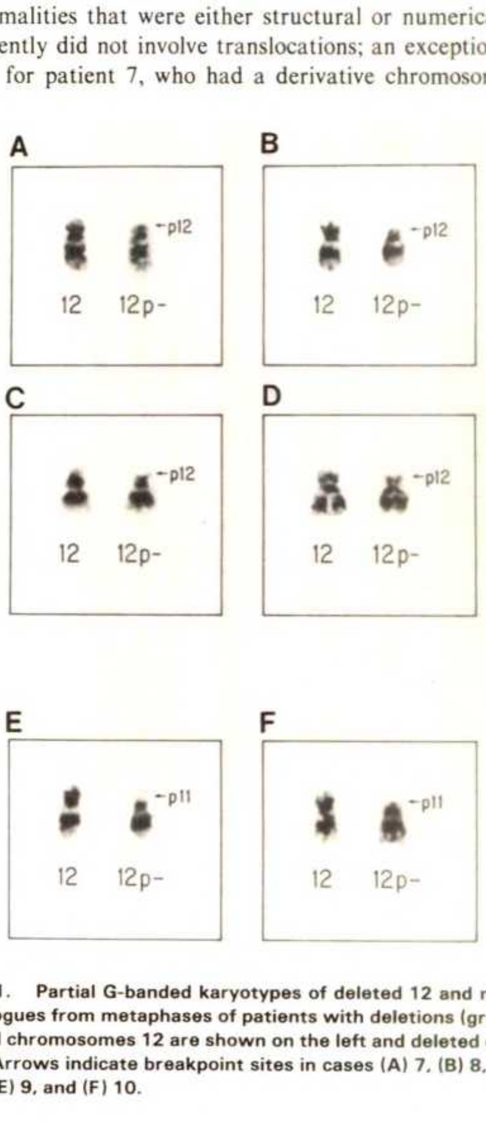

Fig 1. Partial G-banded karyotypes of deleted 12 and normal homologues from metaphases of patients with deletions (group I). Normal chromosomes 12 are shown on the left and deleted on the right. Arrows indicate breakpoint sites in cases (A) 7, (B) 8, (C) 6, (D) 5, (E) 9, and (F) 10.

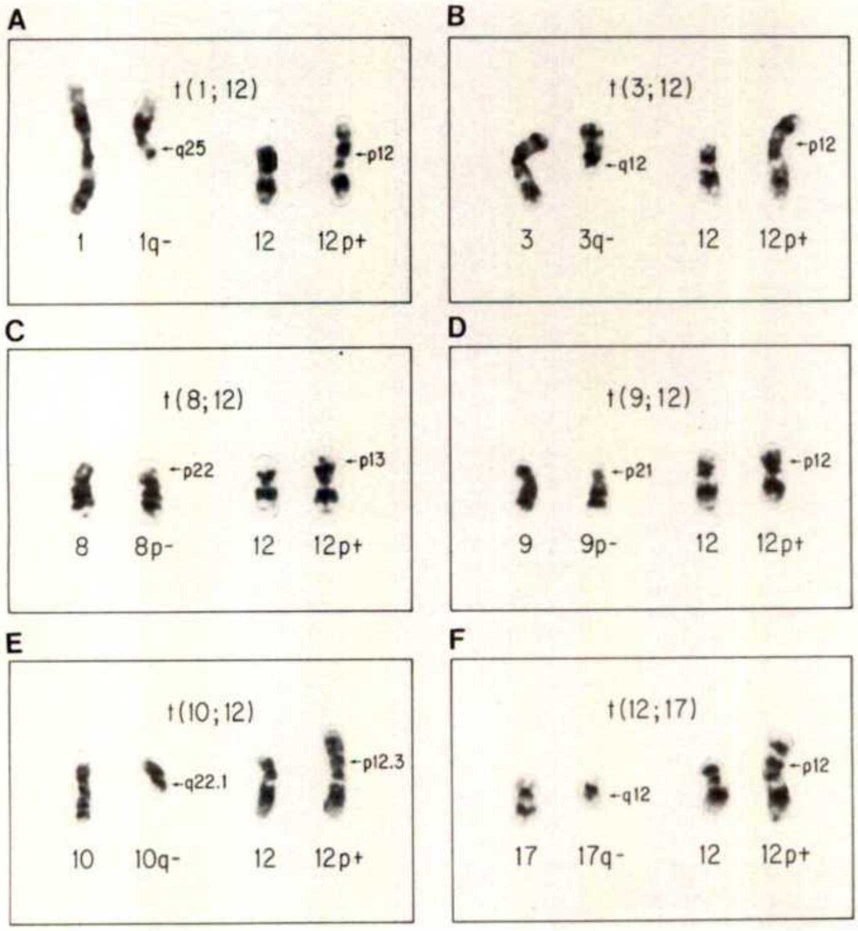

Fig 2. Representative G-banded partial karyotypes of rearranged chromosomes and homologues from metaphases of patients with apparently balanced reciprocal translocations (group II). Panels A through F illustrate changes in patients 11 through 16. The normal chromosomes are shown on the left and the rearranged ones are shown on the right of each pair. Arrows indicate breakpoint sites.

with added DNA of unknown origin. Patients 9 and 10 also presented with a terminal deletion of the p arm of chromosome 12 but at band 11; examples are illustrated in Fig 1E and F. In addition, patient 9 had a complex karyotype with markers of unknown origin. Two apparently unrelated pseudodiploid lines were observed in blast cells from patient 10. Although both independent lines involved chromosome 12, the breakpoints were at different sites in the two stem-lines (p11 and q12).

Group II (apparently balanced reciprocal translocation). A second group was defined by apparently balanced reciprocal translocations between the p arm of chromosome 12 at band 12 and five different chromosomes, as shown in Fig 2A and B and D through F. Lymphoblasts from patient 13 contained an apparently balanced reciprocal translocation between chromosomes 8 and 12, this being the only case with a 12p13 breakpoint (Fig 2C). The karyotypes of the entire group were generally not complex.

Group III (unbalanced translocation). The third group was characterized by unbalanced translocations and complex karyotypes with both numerical and structural abnormalities. To facilitate the description, this group was subdivided into cases with DNA of known and unknown origin translocated to the 12p arm.

Genetic material of known origin was translocated to 12p in five cases (patients 17 through 21, Table 1) (Fig 3A through E). In patient 17, a derivative 12 chromosome was the result of an unbalanced translocation between chromosomes 2 and 12, but with two normal chromosomes 2 also present (Fig 3A). Two related abnormal lines were present due to clonal evolution. The 12p+ in patients 18 and 19 (Fig 3B and C) resulted from an unbalanced translocation between chromosomes 7 and 12. Both cases had identical der(12) chromosomes but different additional chromosome abnormalities. This was the only translocation that was observed twice among all patients with 12p abnormality.

Figure 3D depicts the translocation between chromosomes 9 and 12, with the exact breakpoint in chromosome 9 being uncertain. In all the metaphases containing the der(12), t(9;12), the derivative 9 chromosome was lost, resulting in an unbalanced translocation. Patient 21 (Fig 3E) also had translocated material of known origin (chromosome 17) to chromosome 12p but with the breakpoint assigned to p11. In all the metaphases with the der(12),t(12;17), the small derivative 17 chromosome was missing resulting in an unbalanced translocation. An additional translocation between chromosomes 12 and 17 was found in patient 16 (Fig 2F) but with different breakpoints.

Genetic material of unknown origin was translocated to 12p12 in two cases (patients 22 and 23). In the first (Fig 3F) the 12p+ was present in both the stem-line and a side-line. In the other case (Fig 3G), additional chromosome abnormalities included a possible second translocation between chromosomes 8 and 19.

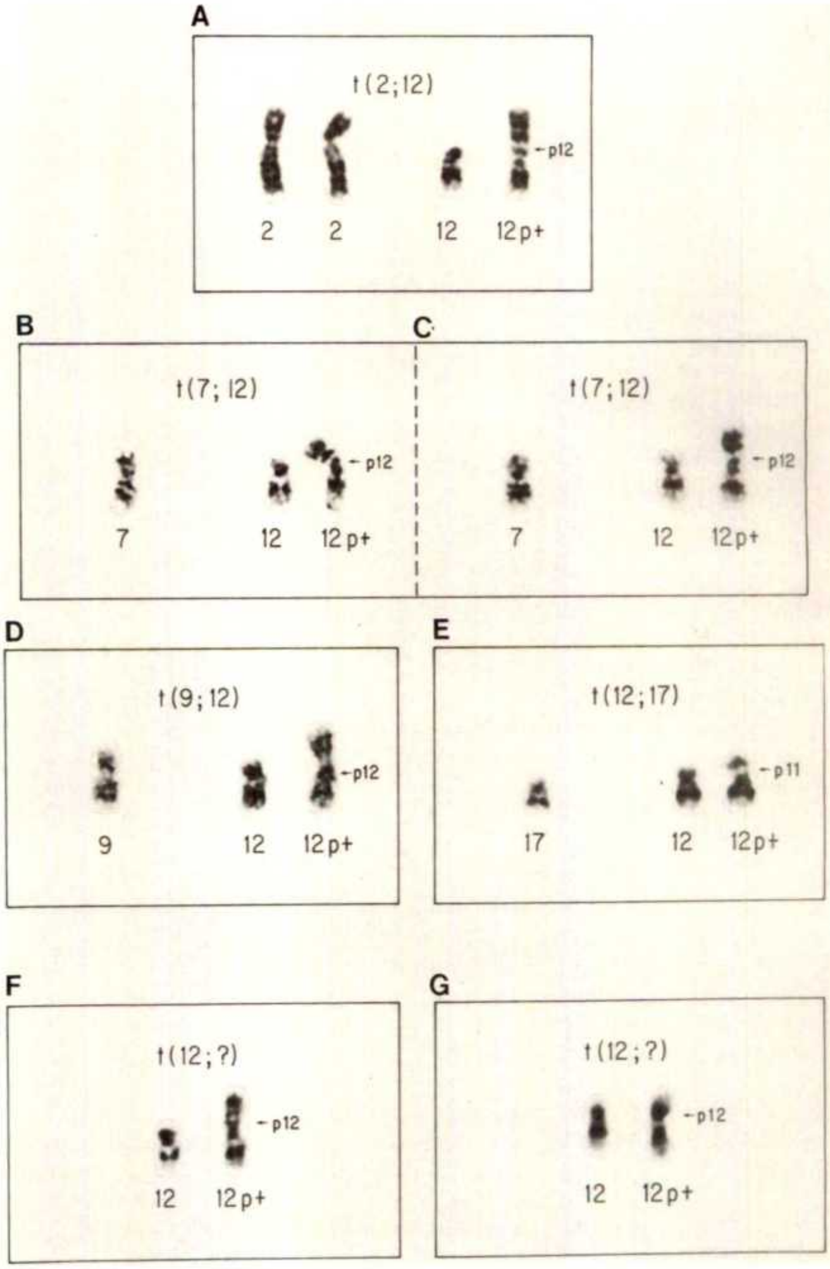

Fig 3. Representative G-banded partial karyotypes of rearranged chromosomes and homologues (when applicable) from patients with unbalanced translocations (group III). Translocated genetic material of known origin: panels A through E (patients 17 through 21) or unknown origin: panels F through G (patients 22 and 23). The normal chromosomes are shown on the left, and the rearranged ones are shown on the right. Arrows indicate breakpoint sites.

General cytogenetic findings. Most of the additional chromosome abnormalities involved structural changes that were varied and inconsistent, except for a deletion of chromosome 9 with breakpoints at p21 (three patients) and an extra chromosome 21 (three non-Down syndrome patients) (Table 1). In contrast to groups I and II, group III had karyotypes of great complexity. In six patients (nos. 4, 8, 12, 17, 18, and 22), there was evidence of karyotypic evolution at diagnosis, suggested by the presence of additional abnormalities not observed in the stem-line. Patient 10 had two apparently independent clones. Although an abnormality of chromosome 12 was involved in both clones, the breakpoint in one was at p11, and in the other at q12.

Patients 16 and 17 were also studied cytogenetically at the time of their first hematologic relapse. Karyotypes of patient 16 determined at diagnosis and relapse were identical; however, patient 17 received a bone marrow transplant after her first relapse but relapsed again 5 months later. At that time, two abnormal lines were present containing markers found at diagnosis, as were additional markers, indicating clonal evolution and progressive growth of the tumor cell population.

DISCUSSION

Reports of abnormalities involving the short arm of chromosome 12 have been sporadic.[21] We have reported four childhood cases[7] and one each has been reported by Whang-Peng and colleagues,[2] Prigogina and colleagues,[8] Morse and colleagues,[9] and Kowalczyk and colleagues.[10] Previous individual reports of the 12p12 abnormality in adults with ALL at the time of diagnosis include only a few cases.[22-25] Recent observations indicate that this abnormality can also be associated with myeloid leukemia.[25,26] In our series of patients with acute nonlymphocytic leukemia, the 12p abnormality was found in only 2 of >100 cases studied. The limited number of children with ALL in earlier studies has precluded estimates of the prevalence of this chromosomal change. From results of the present study, it appears that 12p abnormalities comprise a major cytogenetic group accounting for ~10% of all newly diagnosed patients with this disease.

The relatively low frequency of 12p deletions previously reported most likely relates to the subtlety of this abnormality (Fig 1) and to the quality of sample preparations. The translocation of different chromosomes to the p arm of chromosome 12 (Figs 2 and 3) can result in 12p abnormalities that are more easily detected than simple deletions. Using improved cytogenetic techniques specifically suited to ALL chromosomes, one might expect to find more instances of this chromosomal change in large series of well-studied childhood leukemia patients.

Previous accounts of 12p abnormalities included cases representative of each of the subgroups presented in this study, but recognition of the natural subgrouping of deletions and balanced and unbalanced translocations was not possible because of the limited number of cases evaluated. Future studies may establish that the missing part of the deleted chromosome 12 is translocated to other chromosomes in the complement, although present techniques are inadequate to substantiate this idea. Of the 13 translocations evaluated here, 11 had a breakpoint at 12p12, and one breakpoint each at p11 and p13. In most instances, the abnormal chromosome 12p was involved with different donor chromosomes (1–3, 7–10, and 17), suggesting that breakage in the 12p arm may be a critical event in malignant transformation or in providing the cells with a proliferative advantage.

Because most donor chromosomes in the 12p group of abnormalities are different or, if similar, have different breakpoints, one can argue that the subgroups do not represent specific cytogenetic categories but rather are unique. Nevertheless, the subdivisions we recognized should help to distinguish among major karyotypic differences and should prove useful in future comparative studies.

The only identical translocation observed in this study was a t(7;12)(q11;p12) in two patients, a finding not previously reported. Kaneko and co-workers[24] reported an apparently balanced translocation, [t(12;17)(p13;q12)], that was similar to the abnormality we observed in patient 16, [t(12;17)(p12;q12)], except for a slight difference in the assignment of the breakpoint on chromosome 12, which could have resulted from the different banding techniques used. Patient 21 also had a t(12;17), but it was unbalanced and formed a 12p+, with the 17q arm attached to 12p and the 17p being lost. There were two cases in which other translocations had the same donor chromosomes: a balanced t(9;12) in patient 14 and an unbalanced t(9;12) in patient 20. Hence, our findings indicate a variable composition of the karyotypes in the 12p ALL group. Nevertheless, with future studies of additional well-banded cases, it is likely that additional identical cytogenetic subgroups will be identified. Other chromosome abnormalities most frequently found in our patients were 9p- and +21. A similar 9p deletion was reported previously.[9] Furthermore, Kaneko and co-workers[25] and Kowalczyk and Sandberg[27] suggested that most 9p deletions are found in T cell ALL. All three patients with 9p− in our study had a common ALL immunophenotype. The extra chromosome 21 is a common consistent addition in ALL.[1]

Multiple lines at the time of diagnosis appears to be more commonly observed in ALL than in ANLL.[24] Although at present the clinical and prognostic significance of multiple abnormal lines at diagnosis is unknown, we noted that patients 4, 8, 12, 17, 18, and 22 had related abnormal lines, apparently derived from the same clone. Only patient 10 had two stem-lines, which appeared to be unrelated and to be derived from independent clones. Even though chromosome 12 was involved in both clones, the breakpoints affected the p and q arm independently. Thus, evidence of clonal evolution at the time of diagnosis was found in ~30% of all cases with the 12p abnormalities. This is slightly higher than the 22% reported by Kaneko and co-workers[24] in a consecutive series of 31 pediatric and 19 adult cases with ALL and the 26% in 116 cases included in our current ALL protocol (D. L. Williams, unpublished observations, 1985). Similar karyotypic instability at diagnosis has been reported by others,[22–24] and could indicate a more advanced stage of the disease.

It has been observed that the assigned loci of some human cellular oncogenes correlate with specific chromosomal rearrangements in certain malignancies. The nonrandom 12p12 abnormality reported here thus seems important in view of the recent assignment of the c-Kirsten-*ras* 2 oncogene to 12p12 and q24.2.[11] Furthermore, Popescu and co-workers mapped this oncogene to 12p11.1-12.1 by in situ molecular hybridization.[12] Because some oncogenes may be altered in cancer cells as a result of chromosomal rearrangements, particularly translocation,[28–30] it is believed that each of those recurrent chromosomal changes reflect specific alterations at the molecular level that ultimately trigger the development toward malignancy. Molecular studies of our 12p12 ALL cases are in progress in our institution.

The clinical significance of our findings is not yet known because the follow-up time for many cases has been too short to permit assessment of treatment responses. Even so, from previous findings[1,3] and those of our most recent analysis[6] in which a translocation in ALL was found to confer a poor prognosis, it is likely that patients in groups II and III, both containing translocations, are at higher risk for treatment failure. Group III (unbalanced translocations) had a slightly higher median leukocyte count and by far the most complex karyotypes of any of the three cytogenetic groups we identified. Determination of whether children with 12p abnormalities have different risks of treatment failure, either among themselves or by comparison with other identifiable cytogenetic groups of patients with ALL, requires study of a larger series of patients with such changes.

Metabolism of Ara-C by Blast Cells From Patients With ANLL

By Douglas D. Ross, Bruce W. Thompson, Christopher C. Joneckis, Steven A. Akman, and Charles A. Schiffer

The dose–response relationship between extracellular concentration of cytosine arabinoside (ara-C) and intracellular formation of the putative active metabolites of ara-C [ara-C incorporation into DNA and intracellular pools of ara-C in triphosphate form (ara-CTP)] was investigated in blast cells obtained from patients with acute nonlymphocytic leukemia (ANLL) by exposing these cells in vitro to 10, 100, or 1,000 nmol/L of ara-C. We studied 23 untreated patients who subsequently achieved complete remission (CR) with a regimen using daunorubicin and conventional doses of ara-C (ara-C–sensitive group), and 30 patients judged to be ara-C–resistant either by failing initial induction therapy (16 patients) or by having relapsed on an ara-C–containing maintenance regimen (14 patients). In both patient groups, ara-C incorporation into DNA and intracellular ara-CTP both displayed statistically significant increases in response to increasing extracellular concentrations of ara-C ($P = .0001$ in both cases), with the rate of increase of ara-CTP greater than that of ara-C incorporation. Moreover, blast cells from all patients, even those who were most clinically resistant to ara-C, were able to form ara-CTP and to incorporate ara-C into DNA. Each tenfold increment in extracellular ara-C concentration caused an 8.5-fold increase in ara-CTP, but only a 3.6-fold increase in ara-C incorporation into DNA. Thus, the efficiency of incorporation of ara-C into DNA (defined as the ratio of ara-C incorporation to ara-CTP pools) decreased by 58% with each tenfold increment in the extracellular concentration of ara-C ($P < .0001$), presumably as a result of the inhibitory effect of ara-CTP on DNA polymerase. Using an analysis of covariance, modest differences were found in the levels of the ara-C metabolite variables in the ara-C–sensitive group as compared with the resistant group. However, because there was considerable overlap in ara-C metabolite formation among the patient groups, it was not possible to predict clinical outcome by these in vitro assessments of ara-C metabolism.

THE ANTIMETABOLITE ara-C is one of the most effective agents currently available for the treatment of ANLL in adults. When combined with the anthracycline antibiotic daunorubicin, high remission induction rates have been reported for previously untreated patients.[1,2] Unfortunately, most patients eventually relapse and die of leukemia despite maintenance or continued therapy with ara-C–containing regimens, suggesting the emergence or expansion of ara-C–resistant leukemic cell populations.

Considerable evidence has accumulated concerning the mechanism of ara-C cytotoxicity to established leukemic cell lines. After entering the cell, ara-C must be converted to the triphosphate form (ara-CTP) by a series of kinase enzymes.[3-5] Ara-CTP is considered to be the active metabolic form of ara-C and is a powerful inhibitor of DNA polymerase (DNA nucleotidyltransferase, EC 2.7.7.7), competitive with the natural substrate dCTP.[6-8] Although inhibition of DNA polymerase would surely retard cell growth, inhibition of DNA synthesis per se is not necessarily a cytotoxic event. It has been recognized that ara-C is a weak substrate for DNA polymerase and that small amounts are incorporated into the DNA molecule. In tissue culture systems, incorporation of ara-C into DNA correlates directly with the degree of cytotoxicity.[9] Indeed, recent studies in HL-60 cells[10] of the relationship among ara-CTP pools, formation of ara-C(DNA), and clonogenic survival demonstrated that incorporation of ara-C into DNA was the single most powerful predictor of cell killing by ara-C.

Various biochemical mechanisms of cellular resistance to ara-C have been recognized in cultured cells or in experimental animal tumor models. Cells have been identified with high levels of cytidine deaminase (EC 3.5.4.5) or dCMP deaminase (EC 3.5.4.b) which convert ara-C or ara-CMP to the inactive ara-U or ara-UMP metabolites, respectively.[11] Cells deficient in the nucleoside kinase enzyme (deoxycytidine kinase, EC 2.7.1.74) have been identified,[3,12] which are resistant because of inability to phosphorylate ara-C. Other cells have been found to be resistant to ara-C by their high intracellular levels of dCTP, which inhibit ara-C phosphorylation and which competes with ara-CTP for DNA polymerase.[13,14] A DNA polymerase insensitive to inhibition by ara-CTP or one that fails to recognize ara-CTP as a substrate is another means by which cells can become resistant to ara-C.[15,16] A DNA repair enzyme activity has been described recently that removes ara-C residues from DNA.[17] Thus, enhanced intracellular activity of such an enzyme may be a mechanism of cellular resistance to ara-C. Finally, increased dephosphorylation or intracellular catabolism of ara-CTP offers a potential mechanism of cellular ara-C resistance.[18]

Most of the cellular mechanisms of ara-C resistance mentioned above have been identified in ara-C–resistant cells in culture. However, at present, little data exist as to the mechanism(s) operative in blast cells from leukemia patients clinically resistant to ara-C. Intracellular kinase and deaminase studies have failed to predict clinical outcome,[19,20] as have studies of cellular ability to form ara-CTP,[21,22] although the ability of blast cells to retain intracellular ara-CTP

following in vitro exposure to ara-C has been reported to correlate with remission duration in those patients who subsequently achieved a complete remission.[21,23] More recently, the intracellular pharmacokinetic studies of Plunkett and co-workers[24] suggest that retention of ara-CTP may be a determinant of response to therapy with high-dose ara-C.

Of the mechanisms of cellular resistance to ara-C outlined above, all should be manifested either by diminution in the steady-state intracellular concentration of ara-C, diminution of ara-C incorporated into DNA, or both. It should be noted that those mechanisms which involve enhanced cellular catabolism of ara-CTP and/or enhanced excision and repair of ara-C–induced DNA damage may only become apparent by observing the intracellular half-life ($t^{1}/_{2}$) of ara-CTP (ara-CTP retention) or of retention of ara-C incorporated into DNA following exposure of cells to ara-C.

In the present studies, we measured intracellular steady-state concentrations of ara-CTP and ara-C incorporated into DNA in blast cells from patients with ANLL exposed to varying concentrations of ara-C in vitro, in an effort to understand the dose–response relationship between ara-C and formation of its metabolites in ANLL blast cells, and to determine if differences in these ara-C-metabolic parameters and dose–response can be detected between groups of patients clinically sensitive and resistant to conventional doses of ara-C. Extracellular concentrations of 10, 100, and 1,000 nmol/L of ara-C were used, since 100 to 1,000 nmol/L approximates the steady-state plasma level of ara-C attained during conventional-dose continuous infusion of ara-C.[25]

MATERIALS AND METHODS

Patient selection and characteristics. In all patients, the diagnosis of ANLL was established on the basis of microscopic examination of Wright's-stained specimens of bone marrow, assisted by examination of specially stained specimens [α-napthyl esterase, chloroacetate esterase, terminal deoxynucleotidyl transferase (TdT), Sudan black, periodic acid-Schiff]. These studies were performed between August 1982 and January 1985. The median age of the patients studied was 52 years, with 43% females and 57% males. This approximates the overall demographics of ANLL patients treated at our center. Patients were subdivided into three groups based on their clinical response to ara-C–containing regimens: complete remission (CR) group (ara-C–sensitive patients), no response (NR) group (ara-C–resistant patients); and relapsed (REL) group (ara-C–resistant patients).

Complete remission group. The complete remission (CR) group comprised 23 patients who were untreated at the time of study who subsequently achieved CR with induction therapy consisting of daunorubicin (45 mg/m^2/d; days 1, 2, and 3) and ara-C (100 or 200 mg/m^2/d, days 1 through 7 by continuous intravenous infusion). All but four of the 23 patients in this group have had remission durations >6 months (overall range 2 to 19+ months), and 12 patients (52%) remain in CR at the present time. All patients received ara-C–based maintenance or consolidation regimens. The projected median duration of CR (Kaplan-Meier) for this group is 11 months. All marrows studied were obtained before any treatment was given.

No response group. The no response (NR) group (ara-C–resistant patients) comprised 16 patients who were either untreated at time of study (13 patients) or previously treated (three patients), but who failed to attain remission with an ara-C–containing regimen at any time during the course of their disease. For the previously treated patients, marrow was collected for study after a suitable period elapsed from the last treatment attempt to allow marrow recovery from that treatment (2 to 3 weeks). All patients in the NR group received an initial induction regimen identical to that described for the CR group above. All patients in this group survived their induction attempt and were fully evaluable for response to the ara-C containing regimen.[26]

Relapsed patient group (ara-C–resistant patients). Fourteen patients were studied at time of relapse. Seven patients in this group relapsed while on an intensive ara-C–containing maintenance regimen, and marrow was obtained for these studies prior to further treatment with investigational agents. The other seven patients had a previous CR but had relapsed and failed to respond to an ara-C–containing reinduction regimen. Of the REL group, 7 were in first relapse, 4 were in second relapse, 2 were in third relapse, and 1 was in fourth relapse at the time of study.

No patient was studied during therapy or within 2 weeks of the completion of a chemotherapeutic regimen. The data presented are from 53 different patients. Thus, the patients within a response category are unique to that category. In no case was a patient included in different response categories nor was any patient included twice in the same category.

Bone marrow collection and preparation. Bone marrow (4 mL) was aspirated from the posterior iliac crest of patients using 0.1 mL of preservative-free heparin (1,000 U/mL) as an anticoagulant. Informed consent for marrow collection for this study was obtained as reviewed and approved by the University of Maryland at Baltimore Human Volunteers Institutional Review Board. Marrow was placed in a 15-mL sterile conical centrifuge tube (Costar Plastics, Cambridge, Mass) and then diluted with an equal volume of RPMI 1640 medium (without serum). Marrow cells were dispersed by gentle pipetting and 5 mL of Ficoll-Hypaque ("LSM", Litton Bionetics, Inc) were layered under the marrow suspension. Mononuclear cells were collected at the Ficoll-Hypaque and medium interface after centrifugation (400 g for 40 min, 4 °C).[27] RBCs contaminating the mononuclear cell fraction were lysed by exposure to 0.74% NH_4Cl, following which the partially purified marrow mononuclear cells were washed once with ice-cold RPMI 1640 medium (without serum). Cells were resuspended in a volume of growth medium [RPMI 1640 medium containing 10% vol/vol heat-inactivated (56 °C for 30 min, fetal calf serum (FCS)] sufficient to achieve the desired final cell concentration (~0.8 to 1.2×10^6 cells per milliliter). This procedure yields mononuclear cells of which 80% to 100% have the morphologic appearance of myeloid blast cells when viewed by light microscopy. Viability (trypan-blue dye exclusion) was routinely 80% to 100%. Average blast cell yield from the marrows studied was ~2×10^8 cells.

Blast cell culture and exposure to ara-C or thymidine (dThd). Cells in growth medium (cell concentration, constant within each experiment, ranged from 1 to 2×10^6 cells per milliliter among experiments) were aliquoted into sterile 13 × 100-mm borosilicate glass culture tubes (1.8 mL per tube), and the appropriate amount of ^{3}H-ara-C or ^{3}H-dThd was then added in a volume of 0.2 mL of culture medium to achieve the final desired concentration. Stock 5-^{3}H-ara-C (15 Ci/mmol) was obtained from Amersham/Searle, Inc (Arlington Heights, Ill). The final concentrations in culture/specific activities used were 10 nmol/L (10 Ci/mmol), 100 nmol/L (5 Ci/mmol) and 1,000 nmol/L (1 Ci/mmol). 5-Methyl ^{3}H-dThd (New England Nuclear, Inc, Boston, specific activity 6.7 Ci/mmol) was added to the appropriate culture tubes to achieve a final concentration of 300 nmol/L. Cultures were incubated at 37 °C, 7.5% CO_2, for 22 hours, after which ara-C incorporation into

DNA, dThd incorporation into DNA, and intracellular ara-CTP was determined by methods described below. Zero-time "background" tubes were prepared by incubating cells in the absence of isotope for the 22-hour period and then adding the appropriate amount of ^{3}H-ara-C or ^{3}H-dThd after cooling the cells on ice for 15 minutes. Degradation of ara-C in culture medium alone after 22-hour incubation was minimal. Degradation of ara-C in the blast cell culture ranged from 23% to 37% for 10 nmol/L of ara-C, 11% to 29% for 100 nmol/L of ara-C, and 1% to 22% for 1,000 nmol/L of ara-C, using high-performance liquid chromatography (HPLC), as described previously.[28] The major breakdown product was ara-U. We intentionally avoided the use of cytidine deaminase inhibitors in these studies, since the objective of the experiments was to assess the overall ability of patient-derived blast cells to metabolize ara-C, including the effects of intracellular degradation of ara-C. Incorporation of ^{3}H-dThd into DNA was linear throughout the 22-hour period of incubation.

Determination of intracellular ara-CTP pool size. Following incubation, cultures were chilled on ice for 15 minutes, and cells were collected by sedimentation (400 g for 10 minutes, 4 °C), washed twice with ice-cold phosphate-buffered saline (PBS),[29] and then extracted twice with 200 μL of 60% methanol in H_2O, at 30 °C × 10 minutes. The two methanol extracts of each culture were combined; debris was removed by sedimentation (13,000 g for 10 minutes, 4 °C). Methanol extraction was used since we find[28] that ara-CTP is stable for at least 2 months in 60% methanol at −20 °C. Ara-CTP content of the methanol extracts was determined as reported previously[28] by injecting 80 μL of the extract, along with appropriate internal standards, into a model 3500B HPLC (Spectra-Physics, Santa Clara, Calif) equipped with a 4.6 mm × 25 cm Partisil SAX/10 anion exchange column (Whatman Inc, Clifton, NJ) and a 2.1 mm × 7 cm guard column filled with anion exchange packing. Samples were eluted with a mobile phase of KH_2PO_4 (500 mmol/L, pH 4.6) under isocratic conditions with a flow rate of 1.52 mL/min. Fractions (0.5 mL) of the eluate were collected and absolute radioactivity (DPM) was determined with a Searle Mark III liquid scintillation spectrometer, using quenched internal standards and a ^{133}Ba external standard. Positive identification of the ^{3}H-ara-CTP peak was made with the use of authentic nonradiolabeled ara-CTP (Sigma Chemical Co, St Louis) as an internal standard. This procedure permits effective separation of ara-CTP from dCTP.[28]

Determination of incorporation of ^{3}H-ara-C or ^{3}H-dThd into DNA. Following incubation, ^{3}H-ara-C incorporation into DNA of the blast cells was determined exactly as described previously for HL-60 cells.[30] ^{3}H-dThd incorporation into DNA also was determined by the same procedure except that cells were incubated with ^{3}H-dThd instead of ^{3}H-ara-C. Triplicate determinations were made for each experimental point except in those few patients in whom blast cell yield from the marrow was low, in which case determinations were made in duplicate. Radioactivity in zero-time background tubes was subtracted from the radioactivity of the appropriate experimental tubes. Radioactivity was converted to molar quantities using the known specific activity of the radiolabel.

Statistical methods. The data were analyzed by several statistical methods. When comparisons were made by *t* test, Student's *t* test was used if a comparison was made between two groups of individuals, and the paired *t* test was used when the observations being compared were from the same subject.

The statistical models were fitted using the GLM procedure in SAS (SAS Institute, Cary, NC)[31] using an IBM 4341 computer. Data were missing for one of the three ara-C concentrations for 5.9% of all observations. SAS treated missing values in such a way that any observation that had a missing value for any dependent or independent variable was excluded from the analysis.

RESULTS

Our research objectives were threefold: to study the relationship of dose of ara-C (10, 100 or 1,000 nmol/L) and the formation of potentially active metabolites of ara-C in blast cells from ANLL patients, to determine if the formation of such active metabolites of ara-C could be used to predict clinical response in individual patients, and to determine collectively if differences in ara-C metabolism exist among the three patient groups (CR, NR, and REL). To accomplish these objectives, using an in vitro culture system, we related the extracellular concentration of ara-C (dose) and the clinical response of a patient to three dependent variables which represent important events in ara-C metabolism: the amount of ara-C incorporated into DNA, the intracellular concentration of ara-CTP, and the ratio of these two measures, as a measure of efficiency of ara-C incorporation into DNA. The data and geometric means are shown in Figs 1 through 3. These plots are semilogarithmic. The means ± SE of the three dependent variables for each response group at each extracellular concentration of ara-C used are given in Table 1.

The data presented show a high degree of variability among patients in the amount of ara-C metabolite formed at any dose of ara-C (interpatient variability), contrasting with

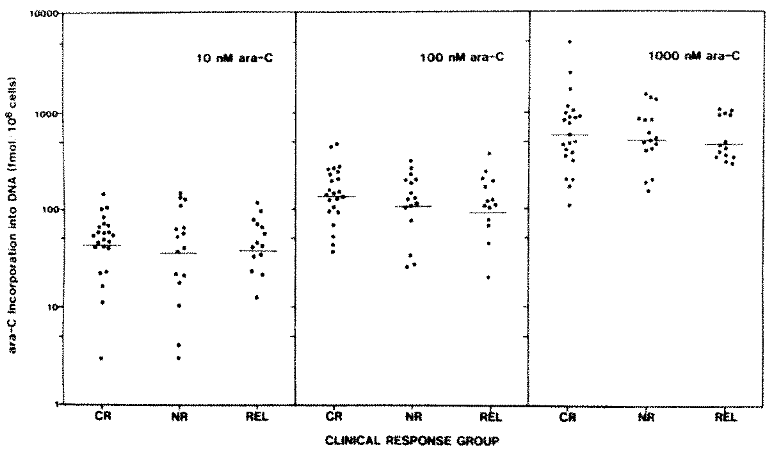

Fig 1. Cytosine arabinoside (ara-C) incorporation into DNA (fmol/10^8 cells) in response to exposure of patient marrow blast cells to 10, 100, or 1,000 nmol of ara-C. Each point represents the mean of duplicate or triplicate determinations obtained from a given patient's marrow blast cells at the dose of ara-C indicated. SDs were <15%. Horizontal bars indicate geometric means.

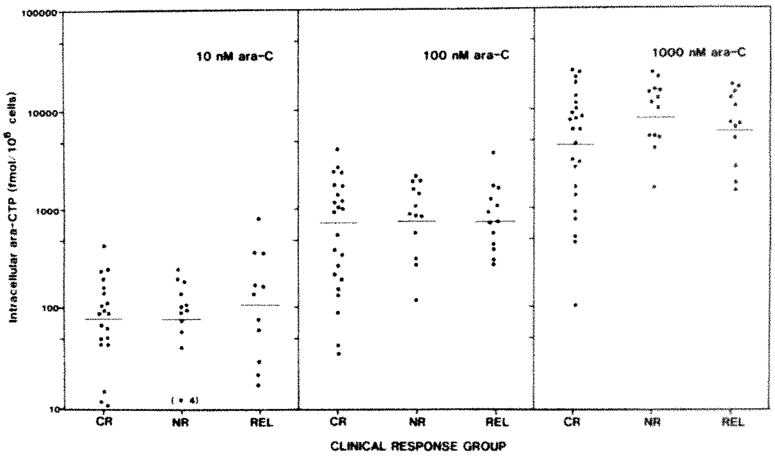

Fig 2. Intracellular cytosine arabinoside in triphosphate form (ara-CTP) formed (fmol/10^6 cells) in response to exposure of patient marrow blast cells to 10, 100, or 1,000 nmol/L of ara-C. Horizontal bars indicate geometric means.

the variability associated with making the measurements of ara-C metabolite in a single patient (experimental variability), which was small. For example, each data point in Fig 1 represents the mean of duplicate or triplicate experimental determinations for a single patient made at the corresponding dose of ara-C, with a SD for each point that was typically $< 15\%$. In addition, what is not apparent from Figs 1 through 3 is the fact that the rank placement of a particular patient's ara-C metabolite measurement at a given dose of ara-C tended to be constant at all other doses of ara-C. Thus, patients with relatively low incorporation at 10 nmol/L of ara-C also tended to have relatively low incorporation at 100 and 1,000 nmol/L as well. Thus, the variability seen in Figs 1 through 3 is really variability associated with differences among patients (interpatient variability) rather than experimental variability associated with the measurement of the ara-C metabolites of a given patient.

The data in Table 1 and Figs 1 through 3 reveal a clear positive relationship between ara-C dose and formation of ara-CTP or incorporation of ara-C into DNA in each clinical response group. Statistically significant increases were present at each increment of extracellular ara-C concentration by paired *t* test ($P < .0001$ in each case). Similarly, the efficiency of ara-C incorporation (ratio of incorporation/ara-CTP) decreased significantly with each increment in ara-C dose ($P < .0001$).

When the various clinical response groups (CR, NR, REL) are compared, Figs 1 through 3 reveal considerable overlap in ara-C metabolite formation among all clinical response groups. Indeed, no significant differences were found in ara-C incorporation, formation of intracellular ara-CTP, or efficiency of ara-C incorporation among the various clinical response groups by Student's *t* test ($P > .05$ in all cases). By inspection of these data, one can see readily that it would be impossible to predict, based on the ara-C metabolic variables of a given patient, the clinical response group in which that patient lies. Thus, at present, we are unable to fulfill our second goal, namely, the development of a test that will predict clinical response in an individual patient.

To ascertain collective trends among the patients studied, the data were evaluated by an analysis of covariance, a statistical method that uses the concepts of both analysis of variance and linear regression.[32] In computing the analysis of covariance, a natural logarithmic transformation was performed to stabilize the variance. For this reason, geometric means are provided in Figs 1 through 3. The results derived from this analysis agree substantially with the results obtained by *t* tests, as described above. Specifically, in relating ara-C dose with metabolite formed, we found that a 3.6-fold increase in ara-C incorporation into DNA and an 8.5-fold increase in intracellular ara-CTP can be expected

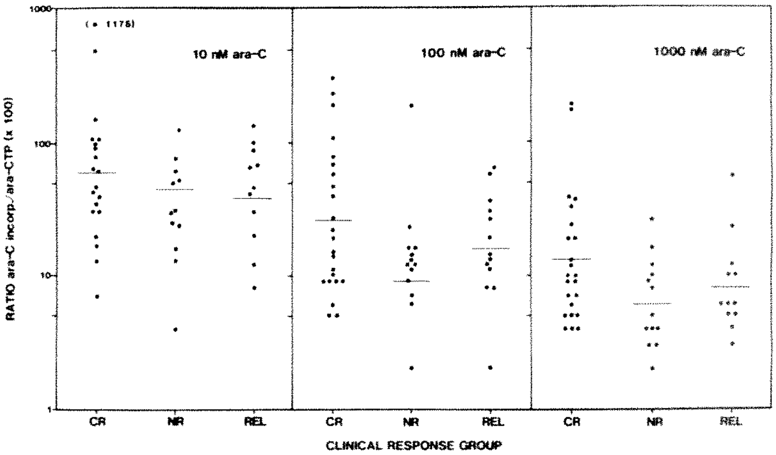

Fig 3. Efficiency of cytosine arabinoside (ara-C) incorporation into DNA [ratio of ara-C incorporation into DNA to intracellular ara-C in triphosphate form (ara-CTP)] expressed as a percentage. The ratio was obtained by dividing the incorporation of ara-C into DNA for a given patient at a given dose of ara-C (data shown in Fig 1) by the corresponding intracellular ara-CTP pool of that patient (data shown in Fig 2). Horizontal bars indicate geometric means.

Table 1. Arithmetic Means ± SE for ara-C Incorporation Into DNA, Formation of ara-CTP and Efficiency of ara-C Incorporation

Clinical Group	Extracellular Concentration of ara-C (nmol/L) 10	100	1,000
CR	54 ± 7 (23)*	165 ± 21 (23)	834 ± 202 (23)
NR	55 ± 12 (16)	131 ± 21 (16)	609 ± 105 (16)
REL	50 ± 8 (14)	126 ± 23 (14)	524 ± 77 (13)
Intracellular ara-CTP (fmol/10^6 cells)			
CR	116 ± 23 (20)	1,006 ± 207 (23)	7,931 ± 1,425 (23)
NR	105 ± 21 (13)	994 ± 188 (13)	10,139 ± 1,850 (13)
REL	179 ± 71 (11)	942 ± 236 (13)	7,781 ± 1,478 (12)
Efficiency of ara-C incorporation into DNA (ratio of incorporation to intracellular ara-CTP for each patient, expressed as %)			
CR	137 ± 59 (20)	57 ± 17 (23)	28 ± 11 (23)
NR	42 ± 10† (12)	25 ± 14 (13)	8 ± 2 (13)
REL	56 ± 13 (11)	23 ± 6 (12)	12 ± 4 (12)

Abbreviations as in Table 1.

*Numbers in parentheses refers to the number of patient marrows studied at that particular ara-C dose level.

†One patient was excluded whose ratio was 3,500%, which is >3 SD from the mean which includes this value.

for each 10-fold increment in the extracellular concentration of ara-C (*P* = .0001 in both cases) (Table 2). Because the rate of increase of ara-CTP was greater than that of ara-C incorporation, the efficiency of ara-C incorporation (ratio of incorporation to ara-CTP) decreased by a multiple of 0.42 (ie, a 58% decrease) with each tenfold increase in ara-C dose (Table 1).

In comparing the various clinical response groups, two separate analyses of covariance were done. The first analysis made the assumption that the patients studied were representative of the general population of patients with ANLL. The second analysis considered a special case in which the patients we studied constituted a unique population, not necessarily representative of the general population of ANLL patients. Small differences in the levels of the three dependent variables were noted (Table 3, adjusted mean values). The CR group, overall, incorporated more ara-C into DNA, had lower intracellular ara-CTP pools, and had a higher efficiency of incorporation of ara-C into DNA than did the other groups (NR and REL). However, in the first analysis, these differences were not statistically significant, consistent with the results of the *t* tests described above. In this case, the large amount of interpatient variability encountered prevented discernment of statistically significant differences. In contrast, the second analysis (which assumed that the patients were an entire population) found that the differences seen in the three dependent variables (Table 2) were large enough that they could not be due to experimental (or assay) variation, and thus they were statistically significant (*P* values, Table 2). However, conclusions drawn from this latter analysis must be limited to the group of patients studied and cannot be extended to the general population of ANLL patients.

Table 2. Analysis of Covariance: Relation of ara-C Metabolic Variable to ara-C Dose

ara-C Metabolic Variable	Slope*	*P* value
ara-C incorporation into DNA	3.6	.0001
ara-CTP	8.5	.0001
Ratio (incorporation/ara-C)	0.42	<.0001

*Slope equals multiple of change in cytosine arabinoside (ara-C) metabolic variable per tenfold increase in extracellular concentration of ara-C.

Six patients in the CR group were studied again at the time of relapse. These patients were not included in the REL group as described above. No statistically significant differences in the metabolism of ara-C were found among these patients at time of relapse as compared with their values before treatment.

Because ara-C is an S phase-specific agent, a possible confounding factor was the rate of DNA synthesis in each patient marrow sample. For each patient, we measured the uninhibited rate of DNA synthesis in the bone marrow cultures during the 22-hour period by measuring the rate of ^{3}H-dThd incorporation into DNA (means for each response group are shown in Table 4). No statistically significant differences in the rate of ^{3}H-dThd incorporation were found among the means of response groups by *t* test (Table 4). When the rate of DNA synthesis in each patient marrow sample was used as a covariable in the analysis of covariance, there was still a highly significant relationship between the ara-C metabolic variable (ara-CTP, incorporation or ratio) and the dose of ara-C.

DISCUSSION

These studies demonstrate a dose–response relationship for ara-C incorporation into DNA and formation of intracellular ara-CTP in blast cells from patients with ANLL. In response to doses of ara-C from 10 to 1,000 nmol/L, the increase in the rate of formation of ara-CTP is greater than that of ara-C incorporation into DNA. Thus, the efficiency of ara-C incorporation into DNA decreased significantly as the extracellular concentration of ara-C was increased. We attribute this effect in part to inhibition of DNA polymerase by the increased intracellular concentration of ara-CTP and in part to the fact that the extracellular concentrations of ara-C used were well below the K_m of deoxycytidine kinase for phosphorylation of ara-C (~20 μmol/L),[4] as evidenced by the linear and nearly direct proportional relationship we observed between extracellular ara-C concentration and intracellular pools of ara-CTP (Table 2). The studies of Riva and colleagues,[33] using high extracellular concentrations of ara-C (in excess of 20 μmol/L), found that the efficiency of ara-C incorporation increased with increasing ara-C dose, presumably due to saturation of the ara-C phosphorylating mechanism. We emphasize that, although we found that efficiency of incorporation decreased with increasing ara-C concentration, in no case did we observe an actual decrease in the absolute amount of ara-C incorporated into DNA by raising the extracellular concentration of ara-C.

The decrease in efficiency of ara-C incorporation with increasing dose of ara-C means that, relative to intracellular ara-CTP, a proportionately larger amount of ara-C is incor-

Table 3. Analysis of Covariance: Adjusted Mean Values

Ara-C Metabolic Variable	Response Group	Adjusted Mean	Units	*P* Value*
ara-C incorporated into DNA	CR	146.9		
	NR	124.6	f mol/10^6 cells	.0079
	REL	109.7		
Intracellular ara-CTP	CR	569.1		
	NR	823.0	f mol/10^6 cells	.0002
	REL	746.2		
Efficiency of ara-C incorporated into DNA	CR	27.4	Ratio: %, ie:	
	NR	15.6	(incorporation ara-CTP)	$<.0001$
	REL	18.4	× 100	

Covariance analysis adjusts the means of the dependent variables (ara-C incorporation, ara-CTP or ratio) by regression to estimates of what they would have been had they had a common independent variable (ara-C dose).[32] Thus, in comparing the various clinical response groups, covariance analysis provided single "adjusted mean" values for each response group. Adjusted mean values were obtained using the least squares option of the GLM procedure of SAS.

*Test of the hypothesis that the three means are equal if the patients studied are considered to be a unique population.

ara-C, cytosine arabinoside; CR, complete remission; NR, no response; REL, relapse.

porated into DNA at an extracellular concentration of 10 nmol/L, as compared with 1,000 nmol/L of ara-C. For example, by means of the slopes shown in Table 2, one can calculate that an increase in extracellular ara-C concentration from 10 to 1,000 nmol/L causes only an ~12-fold increase in ara-C incorporation into DNA, whereas intracellular ara-CTP increases ~70-fold. Ten to 100 nmol/L of ara-C approximates plasma concentrations obtained with "low-dose" ara-C therapy (eg, 10 to 20 mg/m^2 q 12 hours).[34] Perhaps the higher efficiency of incorporation of ara-C into DNA observed at lower doses of ara-C is involved with the efficacy of the "low-dose ara-C" regimen in producing complete remission in the treatment of ANLL, although the precise mechanism involved (differentiative *v* cytotoxic) must remain speculative at this time.

When our patients were considered as a unique population, those who entered CR (estimated clinically to be sensitive to ara-C) incorporated more ara-C into DNA with an equal or lower intracellular pool of ara-CTP than did those who were estimated clinically to be resistant to ara-C. Our finding of higher intracellular ara-CTP pools in clinically resistant patients agrees with the findings of Haanen and co-workers,[35] who observed increased ara-CTP formation in response to 1,100 nmol/L of ara-C in seven of eight ANLL patients at time of relapse as compared with their pretreatment (ie, at time of presentation) values. However, the significance of our findings cannot be extended to the general ANLL population at present since the interpatient variation encountered makes any comparison among response groups statistically nonsignificant when the patients are considered as a sample of the general ANLL population. Similarly, the interpatient variability encountered makes prediction of clinical outcome by such studies impossible in individual patients.

Table 4. In-Vitro Rate of ^{3}H-dThd Incorporation Into DNA (pmols/10^6 Cells ± SE)

Clinical Group	Incorporation
CR (N = 21)	10.9 ± 1.6
NR (N = 14)	17.2 ± 4.0
REL (N = 13)	9.2 ± 2.6

Abbreviations as in Table 1.

Marrow blast cells were incubated in vitro with ^{3}H-dThd in the absence of ara-C. There were no statistically significant differences in the means by Student's *t* test (CR *v* NR, $P > .5$; NR *v* REL, $0.1 > P > .05$; CR *v* REL, $p > .5$).

In cell lines selected for resistance to ara-C, common mechanisms of resistance are impaired phosphorylation of ara-C[3,12] or increased intracellular pools of dCTP.[13,14] Both mechansims should result in a markedly lower intracellular pool of ara-CTP as compared with nonresistant cells. Not only were we unable to demonstrate impaired production of ara-CTP in the resistant patients, but neither did we encounter any patient in this study whose blast cells were totally unable to generate intracellular ara-CTP. This includes patients whom one might consider to be "super-resistant" to ara-C: those in the NR group or those who relapsed while receiving the drug. This finding, combined with the trend for greater efficiency of ara-C incorporation into DNA in our clinically sensitive patients, implies that within our population of ANLL patients with varying clinical sensitivity to ara-C, differences may have existed at the level of DNA polymerase. We cannot, however, rule out enhanced intracellular dephosphorylation of ara-CTP or excision and repair of ara-C/DNA, since these mechanisms may only become apparent when the intracellular retention of ara-CTP or incorporated ara-C is determined, which was not done in our study.

The differences we observed among the clinical response groups were relatively small. For example, the adjusted mean for ara-C incorporation in the CR group was only ~25% greater than those of the NR or REL groups (Table 3). This small difference is not surprising when one considers that in ANLL, the frequency of drug-resistant cells necessary to cause the state of clinical resistance to therapy may be low (eg, <10% of the malignant cell population), since most patients in whom conventional ANLL induction therapy fails to produce CR achieve considerable marrow hypoplasia within 10 to 14 days following therapy. This implies that treatment with an ara-C regimen causes at least 1 log tumor kill (90% reduction of tumor), even in clinically resistant patients. If such is the case, the ara-C metabolites formed by the more populous nonresistant cells may mask the contribution of the resistant cells to the mean ara-C metabolite value obtained for the marrow blast cell sample. Indeed, the variations in ara-C metabolism of the nonresistant cells may have contributed markedly to the interpatient variability we observed in these studies. Thus, in detecting ara-C–resistant cells among a heterogeneous population of blast cells obtained from an ANLL patient, it may be necessary to use a sensitive method capable of analyzing multiple events in single cells. We are currently pursuing such an approach, using flow cytometry.

Effects of Verapamil on In Vitro Intracellular Accumulation and Retention of Daunorubicin in Blast Cells From Patients With Acute Nonlymphocytic Leukemia

By Douglas D. Ross, Christopher C. Joneckis, and Charles A. Schiffer

The effects of verapamil on the intracellular pharmacokinetics of daunorubicin (DNR) in blast cells from the bone marrows of patients with acute nonlymphocytic leukemia (ANLL) were studied to determine whether verapamil was capable of enhancing intracellular accumulation and retention of DNR in ANLL, as has been observed in murine P388 cells resistant to DNR. Seventeen marrows from ANLL patients were studied, 13 of which were from patients who were considered to be clinically refractory to DNR. We took care to include such patients in this study since, in the P388 model, verapamil enhancement of DNR uptake is observed only in cells resistant to DNR. Intracellular accumulation of DNR was studied by exposing blast cells to DNR (1 μg/mL) ± verapamil (6.6 μmol/L) for up to 4 hours. Following a 2-hour exposure of cells to DNR ± verapamil, intracellular retention of DNR was studied by incubating the cells in DNR-free medium for 3 hours. Intracellular DNR/10^6 cells was quantified by fluorometry. In 12 of 15 patient marrows, verapamil failed to enhance intracellular accumulation of DNR. Three patient marrows had a very small increment in DNR uptake in response to verapamil (~14% greater than DNR alone) that was significant ($P < .05$) by paired *t* test. Intracellular retention of DNR ($t^1/_2$) and the area under the intracellular DNR *v* time curve (AUC) were studied in 17 patient marrow specimens. No significant alterations in these parameters were observed in response to verapamil. These data indicate either that verapamil did not substantially enhance DNR uptake or retention in blast cells obtained from ANLL patients who are clinically resistant to DNR, or that the frequency of DNR-resistant cells (ie, verapamil-responsive cells) among the blast cells obtained from these patients was too low to influence the population mean of intracellular DNR as measured in these studies.

DAUNORUBICIN (DNR), an anthracycline antibiotic, is one of the most effective agents currently available for the treatment of acute nonlymphocytic leukemia (ANLL). When combined with the antimetabolite cytosine arabinoside (ara-C), high remission induction rates have been reported for previously untreated patients.[1,2] Unfortunately, most patients eventually relapse and die of leukemia despite continued therapy with DNR-containing regimens, suggesting the emergence or expansion of DNR-resistant leukemic cell populations in patients refractory to treatment.

Although a number of factors have been recognized that may play a role in the expression of cellular resistance to DNR,[3] the mechanisms of anthracycline resistance in human neoplasia are currently unknown. To date, a number of transplantable cells have been made resistant to DNR by exposure to anthracyclines in vivo or in vitro. These include cells of murine (eg, P388, Ehrlich ascites, L5178Y, MDAY-K2)[4-7] and human (HL-60)[8] origin. These resistant sublines seem to share a common mechanistic feature: namely, diminished ability to accumulate intracellular anthracycline as compared to wild-type (sensitive) cells, as a result of active outward transport of drug.[5,7,9-11] Many of these sublines display pleiotropic or multi-drug resistance (eg, to vincristine and many other antineoplastic drugs), and are associated with a cell surface marker (P-glycoprotein).[12]

Recently, calcium antagonists and calmodulin inhibitors have been found to enhance anthracycline intracellular accumulation and cytotoxicity in cell lines resistant to anthracyclines,[13-18] possibly by interfering or competing with the anthracycline for the active outward transport process. Similar effects of verapamil on vincristine uptake and cytotoxicity have been reported for P388/ADR cells,[14-18] a subline of the murine leukemia P388 which is resistant to ADR, DNR, vincristine, and other drugs through the multidrug resistance mechanism. A recent study[19] using blast cells obtained from patients with leukemia, however, reported the failure of verapamil to enhance vincristine uptake. Other investigators[20] failed to demonstrate the ability of verapamil (5 μmol/L) to enhance steady-state intracellular levels of DNR in blast cells from ANLL patients; however, only 5 of the 13 patients studied failed to achieve complete remission with a DNR-containing regimen. Because DNR is such an important element in the modern therapy of ANLL, we attempted to determine whether verapamil (6.6 μmol/L) can enhance in vitro intracellular accumulation and retention of DNR in blast cells obtained de novo from patients with ANLL.

MATERIALS AND METHODS

Patient selection. All patients studied had the diagnosis of ANLL established on the basis of microscopic examination of Wright's stained specimens of bone marrow, with French-American-British (FAB) subcategorization[21] established by examination of stained marrow specimens (α-napthyl esterase, chloroacetate esterase, terminal deoxynucleotidyl transferase, Sudan black, periodic acid-Schiff). FAB classifications and clinical status at the time of study are shown in Table 1. Of the marrows studied, four were from previously untreated patients who subsequently achieved complete remission (CR) with a DNR-containing induction regimen (clinically DNR-sensitive group). However, one of these patients (CB1) had a relatively short remission duration (4 months). These patients were treated with DNR (45 mg/m²/d, days 1, 2, and 3) and ara-C (200 mg/m²/day, days 1 through 7 by continuous intravenous (IV)

DNR, daunorubicin; CR, complete remission; NR, no response to therapy with a DNR-containing regimen; REL, patient in relapse.

infusion). Ten marrows were from patients who failed to achieve CR with a DNR-containing regimen and three were from patients in relapse (DNR-resistant group). Of the marrows from patients who failed to achieve CR, five were from patients prior to treatment, and five were from patients previously treated with a DNR-containing regimen as described above. It should be emphasized that all ten patients who did not achieve CR survived their induction attempt and therefore were fully evaluable for response to the DNR-containing regimen. Of the patients in relapse, patient MP was studied immediately prior to treatment of a second relapse, having had ten previous doses of DNR, 45 mg/m^2. This patient previously had experienced two relatively long remissions (duration 84 and 17 months) following treatment with the regimen of DNR and ara-C described above. Patient PS was studied immediately prior to therapy for a first relapse, having had five previous doses of DNR (45 mg/m^2) as part of initial induction therapy. Remission duration was 6 months. Patient CBI (remission duration 4 months) received three previous doses of DNR, 45 mg/m^2. None of the patients in relapse were treated subsequently with DNR.

Marrow collection and preparation. After informed consent, in accordance with our institutional guidelines, bone marrow (4.0 mL) was aspirated from the posterior iliac crest of patients using 0.1 mL of preservative-free heparin (1:1,000) as an anticoagulant. Freshly aspirated marrow was placed in a 15-mL sterile conical centrifuge tube (Costar Plastics, Cambridge, Mass), then diluted with an equal volume of RPMI medium 1640 (without serum) (GIBCO, Grand Island, Mich). Marrow cells were dispersed by gentle pipetting, and 5 mL of Ficoll-Hypaque ("LSM," Litton Bionetics, Inc, Kensington, Md) was layered under the marrow suspension. Mononuclear cells were collected at the Ficoll-Hypaque and medium interface after centrifugation (400 g for 40 min, 40 °C).[22] RBCs were lysed by exposure to 0.74% NH_4Cl, 4 °C,[23] following which the partially purified marrow mononuclear cells were washed once with ice-cold RPMI medium 1640 (without serum). Cells were resuspended in a volume of growth medium sufficient to achieve the desired final cell concentration (~0.8 to 1.2 × 10^6 cells per milliliter). The growth medium used was RPMI medium 1640 (GIBCO), containing 10% (vol/vol) heat-inactivated (56 °C for 30 minutes) fetal calf serum (FCS) (Sterile Systems, Logan, Utah). This procedure yields mononuclear cells of which 80% to 100% have the morphologic appearance of myeloid blast cells when viewed by light microscopy. Viability (trypan-blue dye exclusion) of the final blast cell preparation was usually > 90%, and was never < 80%. Median blast cell yield from the 17 patient samples was 1.9 × 10^8 cells, with a range of 0.3 to 5.0 × 10^8 cells. DNR uptake and retention studies commenced immediately at this point.

Blast cell culture and exposure to DNR with and without verapamil. Cells in growth medium were exposed to DNR (1 μg/mL) ± verapamil (6.6 μmol/L) at 37 °C, in an atmosphere containing 7.5% CO_2. Cell loss during incubation was minimal. For studies of DNR retention, cells in culture were exposed to DNR ± verapamil for 2 hours, after which the cells were placed on ice for 10 minutes, washed once in ice-cold phosphate-buffered saline (PBS),[24] then resuspended in warm (37 °C) growth medium with a cell density equal to that used during the 2-hour exposure to DNR. Incubation was then continued for 30 to 180 minutes. For cells exposed to DNR + verapamil, verapamil exposure was continued following removal of DNR. Cells were kept ice-cold during washing because influx and efflux of DNR in viable cells is zero when cells are washed under these conditions. Controls (4 °C) consisted of cultures incubated in the absence of DNR and then placed on ice for at least 10 minutes after which DNR ± verapamil was added. The purpose of the 4 °C controls was to control for cell surface or nonspecific binding of DNR and for diffusion of DNR into nonviable cells. The intracellular t½ of DNR was calculated by linear regression analysis; the area under the intracellular DNR *v* time curve (AUC) was calculated by the trapezoidal rule.[25]

P388 cell culture. The methods for culture of P388 cells have been described previously.[26] In brief, wild-type P388 cells (P388/S), obtained from Dr Randall Johnson (Smith, Kline and French Laboratories, Philadelphia), were maintained in liquid suspension culture at 37 °C, in 5% CO_2. The growth medium used was RPMI medium 1640 supplemented with newborn calf serum (10% vol/vol, Flow Laboratories, McLean, Va), L-glutamine (2 mmol/L), penicillin (50 IU/mL), streptomycin (50 μg/mL) and β-mercaptoethanol (0.01 μmol/L). Cells were placed in fresh medium every 5 days at an initial concentration of 2 × 10^5/mL. P388 cells resistant to DNR and ADR (P388/ADR), a gift from Dr Randall Johnson, were maintained in culture under conditions identical to those for P388/S cells described above.

Determination of cellular DNR content by fluorometry. The procedure is a modification of that previously described.[26] At the appropriate time after exposure of cells to DNR, cells were placed on ice for 10 minutes and were then washed once with 5 mL of ice-cold PBS. Following the PBS wash, cells were collected by sedimentation (400 g for 10 minutes at 4 °C), then lysed in 2 mL of 0.54 N H_2SO_4 in 75% (vol/vol) isopropanol. Particulate debris was removed by sedimentation (400 g for 10 minutes), and fluorescence of the supernatant was determined using a spectrofluorometer (Aminco-Bowman, American Instrument Co, Silver Spring, Md) with excitation wavelength of 470 nm and emission wavelength 585 nm. Fluorescence was converted to picomolar quantities of DNR by means of a standard curve, performed concomitantly. Fluorescence of 4 °C controls (background) was subtracted from each experimental point.

RESULTS

Uptake of DNR by leukemic blast cells. Using P388/S and P388/ADR cells in culture, we established experimental conditions that enabled demonstration of significant differences in intracellular pharmacokinetics between the two lines and demonstrated significant effects of verapamil on the intracellular pharmacokinetics of DNR in P388/ADR cells (Figs 1 and 2 show the results of a typical experiment). We

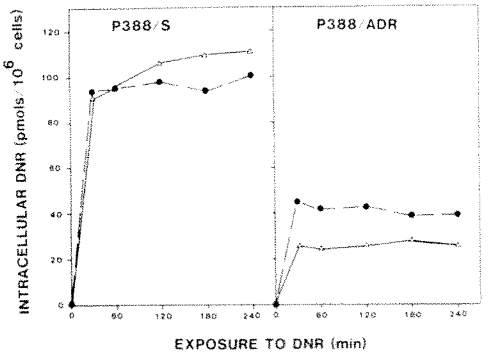

Fig 1. **Kinetics of intracellular accumulation of daunorubicin (DNR) in P388/S or P388/ADR cells. P388 cells in growth medium were incubated with DNR (1 μg/mL) with or without verapamil (6.6 μmol/L) at 37 °C, in 5% CO_2 for the time intervals indicated, after which they were washed once with ice-cold PBS (5 mL) and then lysed in 2 mL of 0.54 N H_2SO_4 in 75% (vol/vol) isopropanol. Particulate debris was removed by sedimentation. Fluorescence of the supernatant was determined (excitation 470 nm, emission 585 nm) using a standard curve to convert fluorescence units to amount of DNR. Data shown are the results of a typical experiment: Δ—Δ, DNR alone (1 μg/mL); ●—●, DNR + verapamil (6.6 μmol/L).**

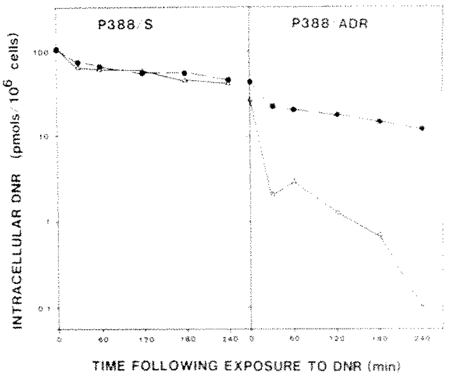

Fig 2. **Kinetics of intracellular retention of daunorubicin (DNR) for P388/S or P388/ADR cells following a 2-hour exposure to DNR (1 μg/mL) ± verapamil (6.6 μmol/L). Following the 2-hour exposure, the cells were washed once in ice-cold PBS, then resuspended in warm (37 °C) growth medium that did not contain DNR but, in the case of cells previously exposed to verapamil, contained verapamil (6.6 μmol/L). At the time interval following removal of DNR (as indicated), cells were removed for determination of DNR content. Data shown are the results of a typical experiment: Δ—Δ, control; ●—●, verapamil, 6.6 μmol/L.**

then applied these experimental conditions prospectively to blast cells obtained from patients with ANLL.

The effects of verapamil on the kinetics of intracellular DNR accumulation were studied in blast cells obtained from 15 marrow specimens (Table 2). One patient in this group (CBI) was studied on two occasions in different stages of his illness. Intracellular DNR content of cells exposed to DNR with or without verapamil for each patient at each time point was compared using the paired *t* test. Blast cells from only three patients (TJ, AG, and GS) displayed a significant increase in cellular DNR accumulation, as compared with control (DNR alone), when verapamil was added to the culture medium. Of these 3 patients, 2 failed to achieve CR with DNR (AG and GS), and 1 was clinically sensitive to DNR (TJ) (Table 1). The magnitude of verapamil-induced enhancement of DNR uptake in these patients was relatively small, however, with an average increment of 14.2% ± 8.2 (SD) above control for each time point. In the remainder of patient marrows studied, verapamil failed to alter blast cell accumulation of DNR significantly (Table 2). When the 15 marrow specimens were considered together, verapamil failed to cause significant differences in the kinetics or magnitude of intracellular DNR accumulation (Fig 3). In contrast, 6.6 μmol/L of verapamil caused an average incre-

P value, paired *t* test. NS, not significant ($P > .05$); (—) not determined; other abbreviations as in Table 1.

Cells in culture were incubated with DNR (1 μg/mL) with and without verapamil (6.6 μmol/L) following which DNR uptake (pmol/10^6 cells) was determined, as described in the Materials and Methods section. Data shown are pmol of DNR/10^6 cells, and are the means of duplicate or triplicate determinations; SE < 10%.

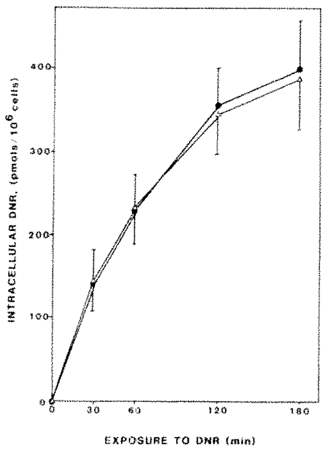

Fig 3. Kinetics of intracellular accumulation of daunorubicin (DNR) in blast cells from 15 marrow specimens obtained from patients with ANLL. The experimental procedures used in these studies were identical to those described in the legend to Fig 1. Data shown are the means ± SE (vertical bars) for all patient studies shown in Table 2. △—△, DNR alone (1 μg/mL); ●—●, DNR + verapamil (6.6 μmol/L).

ment of 64.4% ± 18.9% (SD) at each time point for the DNR-resistant cell line, P388/ADR (Fig 1). The data shown are the results of a typical experiment. Consistent with published reports,[13,17,18] verapamil failed to augment DNR uptake in the wild-type P388/S cells. Verapamil (6.6 μmol/L) failed to increase P388/ADR uptake of DNR to levels comparable to those observed in P388/S cells.

The magnitude and kinetics of intracellular DNR accumulation differ between human ANLL blast cells (Fig 3, Table 2) and murine P388 leukemia cells (Fig 1). P388 cells develop steady-state intracellular levels of DNR within 30 minutes of exposure to DNR, whereas intracellular DNR in human ANLL cells generally continues to increase over 120 to 180 minutes, with the blast cells of a few patients not reaching steady-state intracellular levels of DNR, even after 240 minutes of exposure to DNR (Table 2). In addition, the magnitude of intracellular accumulation of DNR at steady state is greater in cells from leukemic patients than in P388/S cells.

Retention of DNR by leukemic blast cells. The kinetics of elimination of intracellular DNR (Table 3) followed a biexponential pattern in the majority of the patients studied, with an initial, more rapid rate of decay observed within the first 30 to 60 minutes following exposure to DNR. However, in three patients (TJ, JI-1, PS), the decay was monoexponential. No differences caused by verapamil were noted in the initial decay phase (data not shown). The intracellular $t\frac{1}{2}$ (where decay was biexponential, $t\frac{1}{2}$ was based on the terminal intracellular elimination phase) and AUCs following removal of DNR were calculated for the 17 blast cell specimens (Table 4). Correlation coefficients (r) for the regression lines from which $t\frac{1}{2}$ values were calculated averaged .953 ± .057 (SD). Similarly, based on data shown in Fig 2, the AUC and $t\frac{1}{2}$ values were calculated for P388/S and P388/ADR cells, respectively. The results of a typical experiment are shown (Table 4, bottom).

As determined by paired t test, verapamil did not cause any significant alterations in intracellular $t\frac{1}{2}$ or AUC of DNR. In six patient studies (MG, WW, CBI-1, WJ, LE, SL)

(—) not determined; other abbreviations as in Table 1.

Cells in culture were incubated with DNR (1 μg/mL) with and without verapamil (6.6 μmol/L) for 2 hours, following which DNR was removed by washing the cells in ice-cold PBS, then resuspending them in DNR-free medium, after which incubation was continued; samples were removed at the indicated time intervals for determination of intracellular DNR content. For cells previously exposed to DNR + verapamil, the resuspension medium contained 6.6 μmol/L of verapamil, with the exception of patients MG, WW, CBI 1, WJ, LE, and SL, in whom verapamil exposure was not continued following the removal of DNR. Intracellular DNR (pmol/10^6 cells) was determined as described in the Materials and Methods section. Data shown are pmol of DNR retained by 10^6 cells, and are the mean of duplicate or triplicate determinations; SE < 10%.

exposure to verapamil was not continued following removal of DNR from the culture medium. The intracellular t½ or AUC of these patients did not differ as compared with those of patients in whom exposure to verapamil was continued following removal of DNR. Similarly, when studies of cells from these six patients or from the patients clinically sensitive to DNR were removed from this analysis, the result was the same: verapamil failed to prolong t½ or increase AUC. For the 11 patient studies in which exposure to verapamil was continued following removal of DNR, the combined kinetics of DNR retention ± verapamil is shown in Fig 4.

In contrast to the studies of DNR retention in human ANLL blast cells, verapamil increased the intracellular t½ of DNR from 90.1 to 238.7 minutes in P388/ADR cells (Table 4). Similarly, verapamil increased the AUC of DNR retention in these cells from 696 to 4,440 pmol · min/10^6 cells. Verapamil had minimal effects on the intracellular retention of DNR in P388/S cells. The t½ of P388/S cells was comparable to those of ANLL blast cells. The AUC, however, was lower in P388/S cells than in most ANLL blast cell populations studied, a reflection of the lower steady-state intracellular DNR content of P388 cells as compared with human ANLL cells.

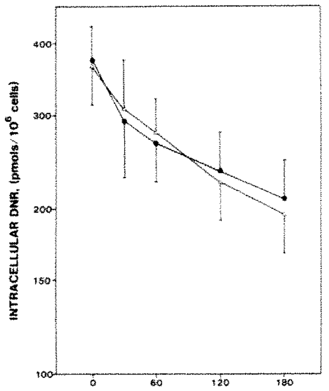

Fig 4. Kinetics of intracellular retention of daunorubicin (DNR) following a 2-hour exposure to DNR (1 µg/mL) ± verapamil (6.6 µmol/L) in blast cells from 11 marrow specimens obtained from patients with ANLL. The experimental procedures used in these studies were identical to those described in the legend to Fig 2. Data shown are the means for all patient studies shown in Table 3: Δ—Δ, control; ●—●, verapamil, 6.6 µmol/L.

DISCUSSION

Neoplastic cellular resistance to antileukemia medications is a major cause of failure of the therapy of ANLL today.[27] Although resistance to DNR probably arises through various mechanisms, the multiplicity and variety of cultured cell lines which display resistance to DNR and to other antineoplastic agents through an enhanced active outward transport (eg, multidrug resistance) mechanism[12] makes it reasonable to postulate that this mechanism will account for at least part of the resistance to DNR that develops in ANLL. Because cells resistant to chemotherapeutic agents by the multidrug mechanism display enhancement of intracellular uptake and retention of drug following exposure to verapamil, the demonstration of an in vitro enhancement of DNR uptake and retention by verapamil in blast cells from ANLL patients who are clinically resistant to DNR may provide indirect evidence for the existence of an active outward transport form of resistance in ANLL. The studies presented in this article cannot confirm this. We are dubious that the minimal enhancement of intracellular DNR accumulation noted in three patients is significant since no differences caused by verapamil were detected in intracellular retention of DNR in these patients. Moreover, one of these patients (TJ) was clinically sensitive to DNR. In addition, since the multidrug resistance mechanism commonly arises as a process of acquired resistance, not primary resistance, the patients in whom we would expect to see the most marked effect of verapamil would be those in the relapsed (REL) group and those in the no response (NR) group who were previously treated. Verapamil failed to influence intracellular pharmacokinetics of DNR in all of these patients.

Kessel and co-workers[20] studied the effects of 5 µmol/L of verapamil on the steady-state intracellular levels of DNR in marrow from 13 patients with ANLL, five of whom could be considered resistant to DNR, and failed to detect any alteration in intracellular DNR caused by verapamil. In this study, the 45-minute exposure of cells to DNR used was assumed to establish intracellular steady-state levels. This contrasts with our study, in which ANLL blast cells required times of up to 180 minutes to achieve intracellular steady-state concentrations (Fig 1).

P388 cells differed considerably from ANLL cells both in the magnitude and in the kinetics of intracellular DNR accumulation. If nonviable cells were present among the ANLL cells, it is possible the continued increase in intracellular DNR observed in ANLL was due to diffusion of DNR into the nonviable cells; this possibility was excluded since marrows with trypan blue viabilities <80% were not studied, and because the fluorescence of 4 °C controls (cells exposed to DNR at 4 °C) was subtracted from each experimental point. DNR will not enter viable cells at 4 °C, and thus fluorescence of the 4 °C controls represents the combined effects of DNR diffusion into nonviable cells and membrane and nonspecific binding of DNR.

Unlike cultured cells such as P388, in which drug-resistant sublines can be obtained with relative homogeneity, the blast cell populations obtained from patients with ANLL are heterogenous. One would expect variation among ANLL blast cell populations in the type of drug-resistant cells and variation within a population of ANLL blast cells in the frequency of drug-resistant cells. It is likely that the frequency of drug-resistant cells in ANLL necessary to cause the state of *clinical* resistance to DNR is quite low (eg, <10%), since most patients in whom therapy with a DNR-containing regimen fails to produce remission achieve considerable marrow hypoplasia within 10 to 14 days following therapy, implying at least 1 log cell kill. Thus, in blast cells obtained from patients clinically resistant to DNR, the contribution of the resistant cells to the population mean may be masked by that of the drug-sensitive cells in the population. Because the methods used measured population means, we feel that the present study, although a logical "first step" in the approach to the problem, does not answer definitively the question of whether verapamil enhances DNR uptake in ANLL, since the methodology used may fail to detect the contribution of DNR-resistant cells if they constitute a relatively small percentage of the total population. To answer this question, one must analyze the intracellular pharmacokinetics of DNR in individual cells within the population of ANLL blast cells, and we are currently pursuing such studies using flow cytometry.

Natural History of Primary Infection With LAV in Multitransfused Patients

By the AIDS–Hemophilia French Study Group

In the course of a prospective study of asymptomatic, multitransfused subjects, seroconversion to human lymphadenopathy-associated virus (LAV/HTLV-III) occurred in 34 hemophilic and in two thalassemic patients. In subjects treated with procoagulant concentrates, primary infection, as evidenced by the development of antibodies to LAV, was a clinically silent event apart from moderate lymph node enlargement in 21% of cases. Concomitant immunologic disturbances mainly affected T lymphocyte subsets. This pattern contrasted with the major lymphadenopathy syndrome observed in the thalassemic patients who received washed erythrocytes from single donors positive for LAV antibodies. Four to 10 months after seroconversion, the incidence of lymphadenopathy reached 46% and the immunologic profile associated inverted T4$^+$/T8$^+$ lymphocyte ratio and markedly increased serum levels of IgG. In multitransfused hemophiliac patients, primary infection with LAV appears to provoke the following simplified sequence of events: decrease of T4$^+$ and increase of T8$^+$ cell counts preceding or concomitant with the occurrence of IgG LAV antibodies. Polyclonal elevation of IgG and lymph node enlargement occur weeks or months later.

© 1986 by Grune & Stratton, Inc.

THE CLINICAL and biological picture of the lymphadenopathy syndrome (LAS), the acquired immunodeficiency syndrome (AIDS)—related complex (ARC), and full-blown AIDS is fairly well characterized.[1] In contrast, little is known about the early course of infection with the human lymphadenopathy-associated virus (LAV), also known as human T-lymphotropic retrovirus III (HTLV-III), aside from an Australian study in homosexuals[2] and a small number of posttransfusion or perinatally acquired cases.[3-6] Among primary infected patients, the factors responsible for the clinical diversity of LAV-related diseases remain to be determined.

In this report, a group of healthy and asymptomatic multitransfused patients consisting mainly of hemophiliac patients was prospectively studied. The clinical and biological changes which preceded, accompanied, and followed primary infection with LAV, as evidenced by a seroconversion, were analyzed. These findings were compared with those observed in groups of seropositive or seronegative subjects. The early stages of LAV infection transmitted by procoagulant concentrates were clinically nearly inapparent and differed from those occurring after other modes of contamination. However, the immunologic disorders were common to both.

MATERIALS AND METHODS

Population Studied

A survey of 425 symptom-free multitransfused patients was undertaken in late 1983 and early 1984 and results of this cross-section study have been reported.[7] This examination is subsequently referred to as initial checkup. Of this population, 146 subjects free of any clinical, hematologic, or immunologic abnormality were selected for a 1-year prospective study. Biological criteria for inclusion in the study were: platelet count >100,000/μL, total lymphocyte count >1,000/μL, ratio of T4$^+$/T8$^+$ lymphocyte subsets >1.0, serum level of IgG up to 1,600 mg/dL, delayed cutaneous hypersensitivity positive for two or more recall antigens, and serum alanine amino transferase less than three times upper normal level.

This selected population included 78 subjects with severe or moderate hemophilia A, 24 subjects with hemophilia A and an anti-VIII:C inhibitor, 26 subjects with hemophilia B, and 18 subjects with chronic anemia related to either thalassemia or sickle-cell disease (Table 1). This last subgroup met all selection criteria except serum level of IgG.

The prospective study was carried out over an average of 14 months per patient (range 11 to 17). Every 4 months (range 3 to 6) a clinical examination and hematologic and virologic checkup was carried out, including enumeration of platelets, lymphocytes, T4$^+$ and T8$^+$ cells, measurement of serum levels of IgG and IgM, and amino alanine transferase and skin tests with seven antigens. IgG antibodies to LAV (LAV Ab) were detected by immunoenzymatic assays.

The LAV Ab status was used as criteria to distribute patients into three groups: LAV Ab positive at onset of the study (45 subjects), LAV Ab negative throughout the study (65 subjects), and seroconverters (36 subjects). By convention, the date of the first LAV Ab sample in a previously LAV Ab-negative subject was considered as the time of seroconversion. In this report, we compare these groups, using the seronegative subjects as control. Results were evaluated on the basis of eight parameters recognized as indicative of LAV infection in the initial cross-section study[7] (Table 2). The amount of replacement therapy received by each patient was the sum of treatment received 1 year prior to entry and during the prospective study (range 22 to 29 months).

The study group comprises the following investigators and institutions: J. P. Allain (coordinator), A. M. Couroucé, and J. Y. Muller, Centre National de Transfusion Sanguine, Paris; J. F. Bach, F. Boiteux, C. Gazengel, R. Girot, and F. Torchet, Hôpital Necker-Enfants Malades, Paris; P. Bardos, A. Goudeau, and G. Lesage, Hôpital Bretonneau, Tours; D. Bastit, Centre Régional de Transfusion Sanguine, Rouen; C. Bosser, Croix Rouge Française, St Alban-Leysse; D. Frommel, INSERM and Hôpital de la Pitié-Salpêtrière, Paris; C. Guerois, and J. Leroy, Hôpital Trousseau, Tours; M. J. Larrieu, Y. Laurian, and T. Lambert, INSERM and Hôpital de Bicêtre, Le Kremlin-Bicêtre; F. Barré-Sinoussi, S. Chamaret, J. C. Chermann, and L. Montagnier, Institut Pasteur, Paris; B. Noël, Centre de Transfusion Sanguine, Chambéry; M. L. Paitre, Centre de Transfusion Sanguine, Le Havre; G. Cordier, S. Lafont, J. P. Revillard, and C. Vincent, INSERM and Hôpital Ed. Herriot, Lyon; F. Brun-Vézinet, and C. Rouzioux, Hôpital Claude Bernard, Paris; and F. Verroust, Croix Rouge Française, La Queue-Lez-Yvelines. This report was prepared by D. Frommel and J. P. Allain.

Mean age (yr)	17.5		16.8		17.6	
(range)	(2–62)		(5–53)		(3–35)	

Treatment with: *factor VIII concentrates; †activated factor IX preparations; ‡regular factor IX concentrate, P.P.S.B.; §chronic anemia patients received monthly transfusions of packed erythrocytes, amounting to 200 mL/kg/yr.

Seropositive subjects. Forty-five hemophiliacs were seropositive for LAV Ab. Twenty-seven of these with complete records have been included in the prospective study. Nineteen patients with hemophilia A were treated with factor VIII; other patients were treated with factor IX concentrates.

Seronegative subjects. Seronegative patients with hemophilia A received factor VIII over a period of 24 months. During the last 12 months, the products were mostly of French origin. Patients with hemophilia A and antibody to VIII:C received either Autoplex (Travenol Laboratories, Glendale, Calif), FEIBA (Immuno AG, Vienna, Austria), or *PPSB* (Centre National de Transfusion Sanguine, Paris) over an average of 23.6 months. Patients with hemophilia B were treated over 25.6 months with *PPSB* concentrate prepared in France. The 16 patients with congenital anemia had received monthly transfusions of packed erythrocytes. Eight of them had undergone splenectomy in the past.

Skin DH positive for fewer than two antigens	3	2	5	6	2

Differences between the groups of patients seropositive for at least 1 year and of those studied 5.3 months postseroconversion are not significant. Skin DH tests were not performed in any of the 27 seropositive patients.

*Seroconversion arbitrarily defined as the first seropositive sample. The intervals of sample collection before and after SC were 5.3 ± 1.8 and 5.3 ± 1.5 months, respectively.

†P = .016 (single-tailed exact test).

‡P = .000027 (single-tailed exact test).

§Cut-off values correspond to −1 SD from mean $T4^+$ count and to +2 SD from mean $T8^+$ count of the seronegative cohort.

‖$P < .05$ *v* preseroconversion.

¶$P < .05$ *v* seronegative.

Seroconverted subjects. The total amount of replacement therapy of these patients was calculated by adding the amount of product received during the year prior to the initial checkup and that which was received from the checkup date to the time of first seropositivity. Hemophilia A patients were treated with factor VIII preparations over a period of 21.8 months. Patients with anti-VIII:C antibodies received one or several of the three products mentioned above over a 22-month period. Hemophilia B patients were treated over 21 months. The therapeutic regime of the two thalassemic patients (aged 8 and 16 years) was identical to that of the 16 patients mentioned above; splenectomy had been performed in one.

Methods

Physical examinations were done blind with regard to the patient's anti-LAV status. Lymphadenopathy is defined as two extrainguinal areas with at least one lymph node >1 cm in diameter. Complete blood cell counts were performed on the model S counter (Coulter) and manually on a few occasions. T lymphocyte-membrane associated phenotypes were determined by indirect immunofluorescence using monoclonal antibodies (Ortho, Raritan, NJ) to helper/inducer ($OKT4^+$) and suppressor/cytotoxic ($OKT8^+$) T cell subsets. Absolute number of cells in each subset was calculated as the proportion of positive cells times the peripheral blood lymphocyte count. Normal values for subjects >10 years of age were 845 ± 110 and 533 ± 129/μL for $T4^+$ and $T8^+$ cells, respectively. In seronegative subjects, these values at two consecutive workups were 1,081 ± 473 and 698 ± 257, respectively. Delayed cutaneous hypersensitivity (DH) to seven antigens was tested with the Merieux Multitest (Lyon, France).[8] For each antigen, the DH was considered positive when the diameter of the induration was at least 2 mm at 48 hours. Because nearly all subjects had been immunized with BCG, diphtheria and tetanus anatoxins, DH was considered decreased when positive result was recorded for fewer than two recall antigens.

Virologic serum markers for hepatitis B, Epstein-Barr virus, and cytomegalovirus (HBV, EBV, CMV) were carried out by standard techniques. Coded samples were tested for IgG LAV Ab according to a slightly modified previously described enzyme-linked immunosorbent (ELISA) method.[9] Controls were run with plates coated with uninfected cells. For reactive sera, antibody titers were determined by comparing serial dilutions of test sample to a reference curve. Anti-LAV antibodies of seroconverters were characterized by an immunoblot technique using a standardized viral preparation[10] and, in some instances, by a radioimmunoprecipitation assay.[11,12]

Data were analyzed by the two-tailed *t* test for unpaired samples and, for comparing proportions, by chi-square statistics or Fisher's exact test.

RESULTS

Two of 18 seronegative subjects with chronic anemia seroconverted during the course of the prospective study. Details concerning these cases have already been reported, along with the presentation of another thalassemic patient who had his primary LAV infection a few weeks prior to the onset of the present study[4]; this subgroup will not be further analyzed. Among 78 hemophiliacs, who were seronegative at entry and monitored at regular intervals, 34 (44%) seroconverted during the 11 to 17 months of follow-up; this corresponds to a 37% annualized rate of seroconversion. There was no significant difference at the 5% level in the prevalence of seroconversion between hemophiliac patients treated with factor VIII or factor IX preparations. However, seroconverters treated with factor VIII or factor IX concentrates had received more products than their respective serologically negative controls ($P < .05$) (Table 1).

Irrespective of their type of therapy, seronegative hemophiliac patients had few abnormalities of index parameters. Two initially had an association of immunologic abnormalities: low $T4^+$ and elevated $T8^+$ counts, $T4^+/T8^+$ ratio <0.50 and serum IgG level above 1,600 mg/dL. This pattern was suggestive of primary infection with LAV, and additional tests were performed to seek evidence for viral transmission; the tests failed to detect LAV Ab. The other 42 subjects (Table 2) had dissociated abnormalities. Eleven patients had $T4^+$ counts <600/μL, causing a $T4^+/T8^+$ ratio <1.00 in six patients.

The occurrence of abnormalities of the eight index parameters in seroconverters was studied. For all patients, a checkup at 5.3 ± 1.8 months prior to seroconversion (in 11 subjects, it corresponded to the initial checkup) and at seroconversion were available; for 24 patients data, obtained at 5.3 ± 1.5 months postseroconversion were also analyzed (Table 2). Both the actual number of results outside normal ranges and differences from initial checkup indicate the presence of clinical and/or biological abnormalities in 19 patients several months prior to detection of anti-LAV IgG. These were essentially decreased $T4^+$ cell count, $T4^+/T8^+$ ratio, and reactivity to skin DH tests associated with elevation of $T8^+$ cell count and IgG level. When these subjects were compared with the group of patients who remained seronegative, it was difficult to evaluate whether the abnormalities were related to patients infected with LAV but still seronegative or to unspecific immunologic disturbances.

At seroconversion, lymphadenopathy was present in 21% of the patients, and the abnormalities seen before seroconversion were either similar or increased in number or magnitude. When differences from initial status were considered, ten subjects had significant changes in T lymphocyte subset counts related to either decreased $T4^+$ count or increased $T8^+$ count and (only once) to concomitant decrease of $T4^+$ and increase of $T8^+$ cells. The mean level of serum IgG was significantly higher than at entry (1,490 ± 460 *v* 1,250 ± 230 mg/dL, $P < .01$).

Examinations postseroconversion revealed a 46% incidence of lymphadenopathy ($P = .016$ *v* preseroconversion checkup), a normalization of $T8^+$ count and, in some cases, of $T4^+$ counts, although the $T4^+/T8^+$ ratio remained abnormal in ten subjects (Table 2). In contrast to this apparent improvement of T cell subset counts, serum IgG levels markedly increased in the 24 subjects who had postseroconversion checkups (mean 1,830 ± 460 mg/dL, $P < .001$ to baseline and $P < .005$ to level at seroconversion). Only two seroconverters remained normal for all index parameters throughout the observation period. Serum IgM levels were similar before and at seroconversion (195 ± 86 mg/dL and 194 ± 114, respectively). A slight decrease remaining below the level of significance was observed after seroconversion (166 ± 50 mg/dL).

Data obtained several months after seroconversion are remarkably similar to those observed in the 27 patients who were seropositive at the onset of the study and remained so over the 14 months of follow-up (Table 2). In this group, the incidence of lymphadenopathy, inverted $T4^+/T8^+$ ratio, and elevated IgG levels were 52%, 48%, and 59%, respectively.

The sequential occurrence of enlarged lymph nodes and elevated serum IgG levels in the seroconverters is shown in Fig 1. Overall, it appears that in a previously healthy patient with hemophilia, the occurrence of lymphadenopathy with concomitant decreased $T4^+$ cell count or increased $T8^+$ cell count, inverted $T4^+/T8^+$ ratio, and elevated serum IgG level are strongly suggestive of LAV infection. In only one patient, a flu-like syndrome was noticed in the weeks preceding

Fig 1. Checkups for lymph nodes (○) and IgG levels (△) in seroconverters. The presence of enlarged lymph nodes in at least two extrainguinal areas or IgG level above 1,600 mg/dL is indicated by closed symbols. SC denotes seroconversion. Intervals before and after SC are defined as in Table 2.

seroconversion. All other patients seroconverted asymptomatically aside from small-size lymphadenopathy.

IgG antibodies to LAV were analyzed by ELISA, immunoblot and, in some cases, radioimmunoprecipitation assay (RIPA) (Table 3). Variations in ELISA titers were observed from patient to patient. For a given subject, titers at seroconversion and in postseroconversion samples were stable, and the median titer was 1:800 in both series. However, in two patients, the titers increased significantly between the two samplings (1:100 to 1:1,600 and 1:200 to 1:1,600, respectively), which may indicate that the first blood specimen was drawn during an ongoing rise of IgG antibodies. ELISA-positive samples were checked by immunoblotting. All but one sample reacted with one or several LAV constitutive proteins. Analysis by RIPA, undertaken for selected samples, further revealed antibody to gp 110 in all 11 samples, including the ELISA-positive, Western blot-negative, second sample of patient 3. In ten postseroconversion sera, additional antibody specificities were detected, mainly against p34. No obvious pattern emerged from comparison of clinical and biological status of patients with antibody titers and/or specificities.

DISCUSSION

The population included in this prospective study was selected on the basis of normality of clinical, hematologic, and immunologic criteria. As expected, although it provided a standard background, the incidence of LAV Ab-positive subjects was lower (35%) than the general incidence observed in the cross-section study (47%),[7] due to the LAV Ab testing which took place several months after the prospective study was launched. The advantage was a relative homogeneity of the seronegative subjects, of whom 44% seroconverted.

Primary LAV infection caused by treatment of hemophiliac patients with factor VIII or IX preparations was a clinically silent event. The only clinical symptom was a moderate enlargement of peripheral lymph nodes. Data obtained from seronegative subjects indicated that, in this population in which 50% of the subjects were <18 years of age, some isolated lymphadenopathy may have other causes. This feature differs strikingly from reports concerning LAV seroconversion related to LAV Ab-positive washed RBCs, whole blood, and plasma, in which massive multifocal lymphadenopathy similar to LAS is described.[3-6,13] Among the 18 patients with congenital anemias enrolled in this study, two 8-year-old boys seroconverted. Both presented with large-size lymphadenopathy in all areas, similar to a patient already reported[4] who seroconverted before entry. In addition, although no other symptom was recorded, one of the two boys had a significant weight loss (4.5 kg) between the time of entry and seroconversion 9 months later. The acute mononucleosis-like syndrome described after accidental needle-stick transmission[14] and in a prospective study among Australian homosexuals[2] seems to correspond to the complete clinical picture of LAV primary infection. In our study, the progressive increase of the prevalence of lymphadenopathy before, during, and postseroconversion and their

persistence over at least 5 months is strongly suggestive of inducement by LAV infection. Similar findings have previously been reported in hemophilic populations.[15-18]

Immunologic disturbances induced by replacement therapy with factor VIII concentrates in seronegative cohorts of hemophiliac patients have been described.[15-19] In this study, elevation of T suppressor cells and sharp rise in IgG serum levels appeared related to the LAV infection (Table 2). This observation made in the seroconverters was confirmed by our findings in the seropositive group of patients. Persistent lymphadenopathy and elevation of T8$^+$ cells and serum IgG levels may thus be considered as reliable markers of LAV infection, particularly when they are associated (Fig 1). However, any of these three parameters can be separately altered over time in a given subject. In contrast, low T4$^+$ cell counts were randomly distributed among seronegative and seropositive groups. A moderate decrease in T4$^+$ may therefore reflect in part the effects of replacement therapy itself. T helper cells are known to be the privileged target of LAV; our data, however, did not single out a specific defect of this subset, which seems more prone to abnormalities related to other causes, such as EBV, HBV, or CMV chronic infections. Repeated evaluation of delayed hypersensitivity for seven antigens by the Multitest appeared to be a useful tool for evaluation of immune reactivity. Although this repetition has been reported to modify the extent of response, the number of responsive antigens was not affected.[8]

From the collected data, a simplified sequence of event appears to be: decrease in T4$^+$ and increase of T8 counts preceding or concomitant with occurrence of IgG LAV Ab, followed by polyclonal elevation of circulating IgG and lymph node enlargement (Fig 2).

Our data confirm previous findings demonstrating that seroconversion is not a reflection of an immunization by incomplete noninfective viral antigens but rather is a replicating virus hosted by T lymphocytes.[20] It is possible that the mild primary infection syndrome observed in hemophiliac patients is caused by a small number of infective particles deriving from few donors whose plasma is highly diluted in a large pool. A possible attenuation of viral pathogenicity related to purification procedures and freeze-drying may also play a role. Whether such a small infective dose carries a better long-term prognosis remains to be evaluated.

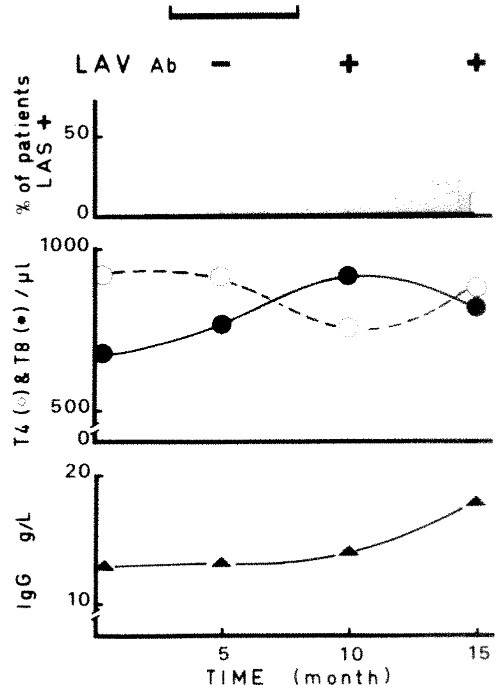

Fig 2. Schematic diagram picturing the sequential values of T lymphocyte subset counts, serum IgG levels (patients <10 years of age omitted), and prevalence of lymphadenopathy (LAS) in seroconverting hemophiliac patients. Bar (top) corresponds to the likely period of LAV contamination. Means of data from 24 patients >10 years of age were used to draw this diagram.

Covalent Crosslinking of von Willebrand Factor to Fibrin

By Masao Hada,* Marek Kaminski, Paula Bockenstedt, and Jan McDonagh

Factor XIIIa crosslinks a limited number of substrates via $\epsilon(\gamma$-glutamyl)-lysyl bond formation. It crosslinks fibrin to itself, α_2-plasmin inhibitor and fibronectin to fibrin, and fibronectin to collagen. Results presented here show that plasma von Willebrand factor (vWF) is a substrate for factor XIIIa and can be crosslinked to fibrin during gel formation. vWF-fibrin crosslinking was studied in purified systems and in plasma with ^{125}I-vWF and ^{131}I-fibrinogen. vWF incorporation into fibrin increased with time or increasing factor XIIIa. After electrophoresis of dissolved clots, distribution of ^{125}I and ^{131}I was measured and showed that vWF was crosslinked to the α chain of fibrin and entered the high-mol-wt α polymer. vWF-fibrin crosslinking decreased the initial rate of α polymer formation. Crosslinking of vWF polymer to itself could not be demonstrated under physiologic conditions but occurred if vWF was reduced first. Factor XIIIa catalyzed incorporation of putrescine into both monomeric and polymeric vWF. Altogether, these studies indicate that factor XIIIa can readily form covalent bonds between glutamine in vWF and lysine in fibrin α chains. This reaction occurs readily in vitro when plasma clotting is slow and may occur in vivo under similar conditions.

VON WILLEBRAND factor (vWF) is a large, multimeric plasma glycoprotein component of the factor VIII complex. vWF is important in the initial adhesion of platelets to the vascular subendothelium, and the molecular mechanisms by which it facilitates platelet adhesion have been partly elucidated. vWF has been shown to bind both to the platelet receptors, glycoprotein Ib[1,2] and glycoprotein IIb-IIIa,[3,4] and to collagenous[5,6] and noncollagenous components of the subendothelium,[7] thus forming a bridge between activated platelets and damaged endothelium.

Fibrinogen, in particular, and also fibronectin, bind to the platelet glycoprotein IIb–IIIa receptor, which raises the possibility of specific vWF interaction with these proteins that also facilitate platelet adhesion and aggregation.[8-10] Purification of each of these proteins from plasma is hampered by contamination with the other two. Fibrinogen is necessary for the cryoprecipitation of vWF, and both fibrinogen and fibronectin are required for heparin-induced precipitation of vWF.[11,12] vWF also precipitates in the presence of fibrin–fibronectin complexes.[11] The conditions under which vWF forms aggregates with fibrin(ogen)–fibronectin are nonphysiologic, and it is difficult to determine if such aggregate formation has physiological relevance. However, it is possible that similar interactions between fibrin and vWF may occur at sites of vessel wall injury where glycosaminoglycans on damaged endothelial surface or in the matrix may be available.

It has previously been reported that serum from hemophiliacs with long clotting times contains less vWF than do the corresponding plasma samples.[13,14] This was only observed in in vitro clotting systems when the clotting time was prolonged. However, it was also observed in normal samples when the clotting time was long.[14] From this it was hypothesized that a time-dependent interaction between vWF and fibrin could occur during clotting under appropriate conditions. Further studies with factor XIII-deficient or factor XIII-supplemented plasma indicated that this interaction might involve covalent crosslinking of vWF to fibrin.[14]

In the present study, the interaction of vWF with fibrin in purified test systems and in plasma clotting systems has been characterized. Evidence is presented that vWF is a substrate for the transglutaminase reaction catalyzed by factor XIIIa. Monomeric vWF can covalently crosslink to itself, but the polymeric forms do not. However, under appropriate conditions vWF polymers can be covalently crosslinked to the α chains of fibrin during the process of fibrin gel formation. This reaction can occur in plasma and requires only that the gelation process be long.

MATERIALS AND METHODS

von Willebrand factor purification and radiolabeling. vWF was purified from human plasma (obtained from the American Red Cross Blood Services, Northeast Region) by a modification of the procedure of Kao and colleagues,[15] as previously described.[16] Protein concentrations were determined by the method of Lowry and co-workers[17] and by electroimmunoassay. Purity was assessed by sodium dodecyl sulfate (SDS) gel electrophoresis under reducing conditions.[18] vWF activity was assayed as ristocetin-dependent platelet agglutinating activity (vWF:Ag).[16] Purified material was labeled with ^{125}I by the Iodobead procedure.[19] One Iodobead was preincubated with 0.5 to 1.0 mCi Na^{125}I and 100 μL of 50 mmol/L of Tris-0.15 mol/L of NaCl–0.02% azide, pH 7.2, for 10 minutes at room temperature; 500 μg of purified vWF was then added. After 10 minutes, iodination was stopped by transfer of the vWF solution to a column of Sephadex G-25 (0.7 × 10 cm) preequilibrated with Tris-saline buffer containing 1 mg/mL of bovine albumin. Labeled vWF was eluted in the same buffer. With this procedure, the average specific radioactivity of ^{125}I-vWF was 0.20 to 0.25 μCi/μg of protein. The vWF concentration agreement between the two methods, electroimmunoassay and vWF:Ag was good ($N = 16$, $r^2 = 0.993$), indicating that radiolabeling did not have a deleterious effect on functional properties of vWF.

Fibrinogen preparations. Fibrinogen was purified from human plasma by $(NH_4)_2SO_4$ precipitation.[20] The product was 93% clottable and showed the three expected bands (Aα,Bβ,γ) on reduced SDS gels. For some experiments, fibrinogen was treated with *p*-hydroxymercuribenzoate to inactivate trace amounts of factor XIII in the preparation.[21] After this treatment, the clottability was 91%. vWF contamination in the fibrinogen preparations was determined by electroimmunoassay and ranged from 15 to 25 μg/mg of fibrinogen.

In some experiments, this was used as a source of vWF. In experiments using radiolabeled fibrinogen, the fibrinogen preparation was freed of vWF by affinity chromatography on fibrin monomer Sepharose before labeling.[22] vWF was eluted by 50 mmol/L of Tris-H_3-PO_4–0.1 mol/L of NaCl-25 mmol/L EACA, pH 7.6. Fibrinogen was eluted by Tris-H_3PO_4-EACA buffer containing 1 mol/L of NaCl, pH 4.1. The thrombin inhibitor, D-phenylalanyl-L-prolyl-L-arginine chloromethyl ketone (PPACK) (Calbiochem-Behring, La Jolla, Calif), was added to the sample and to the elution buffers. After elution, fibrinogen was dialyzed *v* Tris-saline, pH 7.4, and concentrated by precipitation with polyethylene glycol. This fibrinogen was labeled with ^{131}I by the solid-phase lactoperoxidase-glucose-oxidase procedure using Enzymobeads (Bio-Rad, Richmond, Calif).[22] The specific radioactivity was 0.025 to 0.035 $\mu Ci/\mu g$ of protein.

Factor XIII. Factor XIII was purified from human plasma or placental concentrate as previously described.[23] Placental concentrate (Fibrogammin) was kindly provided by Behringwerke A.G.; it contained the intracellular form of factor XIII (equivalent to platelet factor XIII, A_2) and primarily albumin. Because in these studies the same results were obtained with purified factor XIII and with the concentrate, the concentrate was routinely used without further purification. In the concentrate, 1 U is equal to the amount of factor XIII in 1 mL of normal plasma. Factor XIII activity was assayed by the ^{14}C-putrescine incorporation assay with activation of the zymogen by thrombin and $CaCl_2$.[24] In experiments in which factor XIIIa was added directly to the test system, the zymogen was treated with 1 U/mL of thrombin and 10 mmol/L of $CaCl_2$ for 30 minutes at room temperature. After cleavage of the factor XIII A chain, thombin was inhibited by addition of PPACK or hirudin, which did not interfere with factor XIII enzyme activity.

Putrescine incorporation into vWF. The substrate suitability of vWF for the crosslinking reaction catalyzed by factor XIIIa was determined by measuring the covalent incorporation of ^3H-putrescine or ^{14}C-putrescine (New England Nuclear, Boston) into purified vWF in the presence of factor XIIIa. The following experimental conditions were used: 0.99 μmol/L of vWF, 50 mmol/L of putrescine, 16.7 mmol/L of dithiothreitol, 6.7 mmol/L of $CaCl_2$, and 21 U/mL of thrombin. Factor XIII was varied from 0 to 5 U/mL. In some experiments hirudin (83 U/mL) was added after factor XIII activation and before addition of vWF to the test system. Incorporation of putrescine into vWF was allowed to proceed at room temperature for 2 minutes to 18 hours. The reaction was terminated by spotting samples on filter paper and immediately immersing them in cold 10% trichloroacetic acid (TCA) for 20 minutes. Filter papers were transferred to 5% TCA and then washed three times each in ethanol-acetone (1:1) and 100% acetone. Samples were air dried and counted in a scintillation counter. The recovery of vWF by this technique was 97.8% to 100%.

Covalent incorporation of putrescine into vWF was also analyzed by SDS gel electrophoresis. Samples were similarly prepared (50 mmol/L of ^3H-putrescine, 0.99 μmol/L of vWF, 6.7 mmol/L of $CaCl_2$, 21 U/mL of thrombin, 0 to 5 U/mL factor XIIIa); incorporation was allowed to proceed for 18 hours at 4 °C; it was terminated by addition of SDS sample buffer containing dithiothreitol, followed by incubation at 100°C for 5 minutes. SDS gel electrophoresis was carried out on 4% cylindrical gels under reducing conditions.[25] Gels were sliced in 1-mm sections and dissolved in 30% H_2O_2 overnight at 56 °C, and total radioactivity was measured.

Covalent crosslinking of vWF to fibrin in a purified system. For these experiments factor XIII (0 to 50 U/mL) was preactivated with thrombin (5 U/mL) and $CaCl_2$ (10 to 100 mmol/L) for 30 minutes at 37 °C. In the second step, the activation mixture was diluted fivefold to tenfold with ^{131}I-fibrinogen and ^{125}I-vWF, and clotting was allowed to proceed for 2 minutes to 18 hours. Fibrinogen, which had no factor XIII activity, was 1.4 to 1.9 mg/mL; vWF was 48 to 56 μg/mL for the test samples and 0 in the controls. Test systems also contained 10 μL ^{131}I-fibrinogen (78,300 cpm/μg) and 10 μL ^{125}I-vWF (10,700 cpm/μg). At various time intervals, clots were separated, compressed to remove the fluid, and washed with Tris-saline containing 50 mmol/L of EDTA. Total radioactivity in the clots and supernatants was measured. Supernatants were also assayed for vWF antigen by electroimmunoassay. Washed clots were dissolved in urea–SDS–DTT sample buffer and analyzed by SDS gel.[25] After electrophoresis, the gels were sliced in 1-mm sections and counted in a γ-spectrometer.

Covalent crosslinking of vWF to fibrin in a plasma system. Normal plasma (fibrinogen, 2.4 to 2.6 mg/mL; vWF antigen 10 to 15 μg/mL) and plasma from a patient with severe hemophilia A (fibrinogen, 2.6 mg/mL; vWF antigen, 20 μg/mL) were allowed to clot by addition of $CaCl_2$ (10 mmol/L). In some experiments, clotting times were adjusted by adding hirudin to normal plasma or thrombin to factor VIII-deficient plasma. In some experiments, trace amounts of ^{131}I-fibrinogen and ^{125}I-vWF were added to the plasmas before clotting. Clots were allowed to form for 3 hours at 37 °C and overnight at 4 °C. Clots and sera were then analyzed for vWF and fibrin as in the test system, using purified reagents.

Electroimmunoassay. vWF antigen was quantitated by Laurell immunoelectrophoresis.[26] Electrophoresis was performed in 0.9% agarose gels, containing 0.65% monospecific rabbit antiserum to human vWF (Calbiochem-Behring, Marburg, FRG), in Tris-barbital buffer (pH 8.6, ionic strength 0.03) at constant current (1 mA/cm) at 4 °C for 18 hours. Gels were stained with Coomassie blue and destained with glacial acetic acid–methanol–water. There were no changes in vWF concentration when factor XIII was added to the mixture.

RESULTS

Measurement of the covalent incorporation of a lysine analogue into a protein as a function of factor XIII activity is a straightforward way to determine if the protein contains glutamine(s) that may be suitable substrate(s) for transglutaminase catalyzed crosslinking. Figure 1 shows the results of such an experiment for purified, monomeric vWF. In the presence of factor XIIIa, vWF covalently incorporated putrescine in the expected time-dependent and concentration-dependent manner. At 1 hour, 0.97 μmole of putrescine

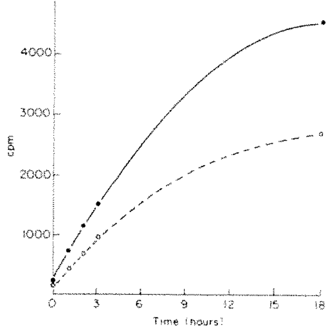

Fig 1. Covalent incorporation of ^3H-putrescine into von Willebrand factor by factor XIIIa. Factor XIII was activated with thrombin and $CaCl_2$ plus DTT, and then hirudin was added. vWF (0.495 mg/mL) was added to factor XIIIa and ^3H-putrescine. At various times, aliquots were placed on filter paper, washed with TCA, ethanol:acetone, and acetone, and counted; (---) 1 U/mL of factor XIII; (——) 5 U/mL of factor XIII.

was covalently bound per μmole of vWF monomer when vWF was incubated with 1 U/mL of factor XIIIa. Increasing the factor XIIIa to 5 U/mL increased the incorporation at 1 hour to 1.55 μmoles of putrescine incorporated per micromole of vWF monomer. These results clearly indicate that under certain experimental conditions factor XIIIa readily incorporates putrescine into glutamine residues of monomeric vWF. Further studies to define the conditions for this reaction showed that both thrombin and reducing agent enhanced the rate of incorporation, indicating that thrombin proteolysis and reduction exposed additional glutamines that could participate in crosslinking. After 18 hours of incubation, there was ~20% enhancement in the total putrescine incorporation in the presence of thrombin.

Further investigation of vWF crosslinking showed that when purified vWF was fully reduced and incubated with factor XIIIa, not only did monomeric vWF incorporate putrescine, but it also covalently crosslinked to itself (Fig 2A). In contrast, incubation of vWF polymer with factor XIIIa did not result in vWF crosslinking to itself (Fig 2B). As shown in Fig 2A, vWF was fully reduced by addition of dithiothreitol to the incubation mixture. After 18 hours, samples were subjected to SDS gel electrophoresis in reducing buffer; gels were then sliced into 1-mm sections and radioactivity was measured. The results show radioactive bands migrating in positions corresponding to vWF monomer, dimer, and trimer, as well as higher polymer formation. This indicates that vWF monomer has both glutamine and lysine groups that can participate in the crosslinking reaction. However, incubation of purified vWF polymer with factor XIIIa resulted in incorporation of putrescine but not in covalent crosslinking of vWF with itself, indicating that in the polymeric state only glutamines, not lysines, were available for crosslinking.

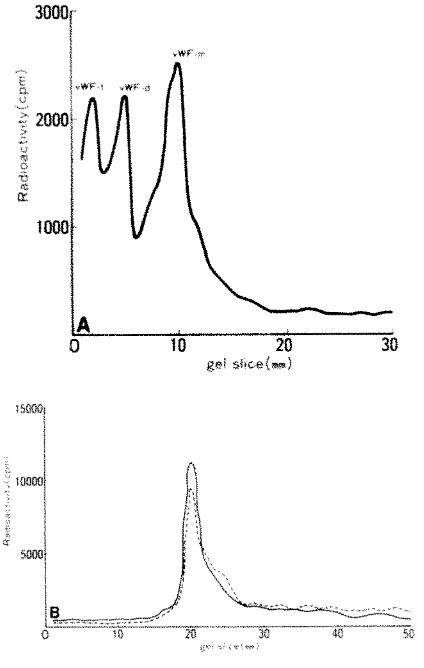

Fig 2. Crosslinking of von Willebrand factor by factor XIIIa. (A) Monomeric vWF was incubated with factor XIIIa and ^{3}H-putrescine as in Fig 1 with 1 U/mL of factor XIII. The crosslinking reaction was terminated by mixing samples with sodium dodecyl sulfate (SDS) reduced gel electrophoresis buffer, and electrophoresis was carried out in cylindrical gels. Gels were cut in 1-mm transverse sections, dissolved in H_2O_2, and counted. (B) Polymeric ^{125}I-vWF plus $CaCl_2$ was incubated in the presence (---) or absence (——) of factor XIIIa for 4 hours and then analyzed by reduced SDS gel electrophoresis. Gels were cut in 1-mm sections and counted.

Covalent crosslinking of vWF to fibrin was investigated in test systems containing purified vWF (trace-labeled with ^{125}I) with purified fibrinogen (trace-labeled with ^{131}I). Factor XIII was activated with thrombin and $CaCl_2$, and this mixture was added to the fibrinogen–vWF mixture to initiate clotting and crosslinking. All the clotting reactions were carried out in the absence of reducing agents, that is, with intact fibrinogen and vWF polymer. In some studies, after termination of the reaction, the reaction products were reduced and analyzed on reduced SDS gels. Figure 3A shows the covalent crosslinking of vWF to fibrin at various factor XIIIa concentrations. In this experiment, the molar ratio of fibrinogen to vWF monomeric unit was 30:1; at the highest

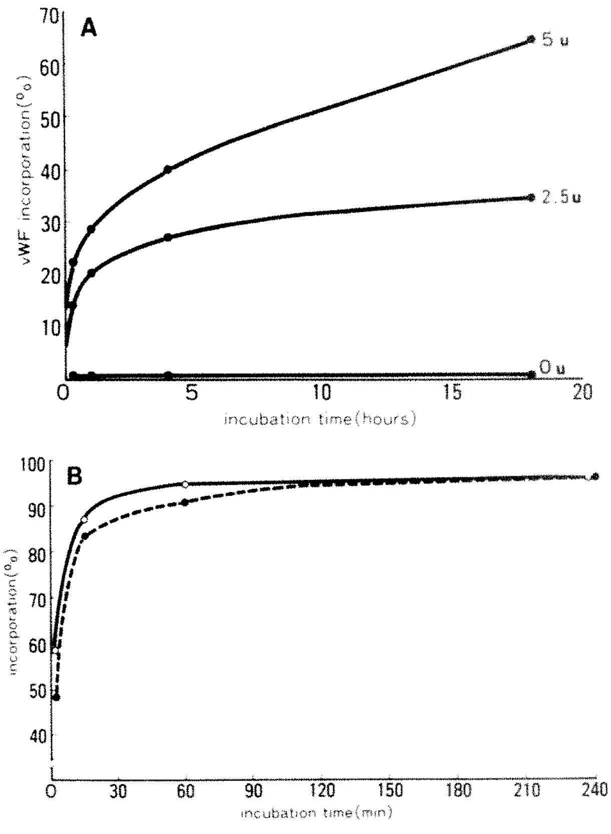

Fig 3. Incorporation of vWF into fibrin gels. (A) Factor XIIIa dependence. Fibrinogen (factor XIII-free) plus vWF (molar ratio 30:1) was clotted with thrombin and $CaCl_2$ and varying concentrations of factor XIII. Factor XIII concentration is shown at the right of each curve. At various times, clots were separated from fluid, washed in EDTA, and vWF was measured by electroimmunoassay. (B) Effect of vWF on fibrin incorporation. Samples were similarly prepared except that trace ^{131}I-fibrinogen was added. Fibrin in the washed clots was measured by radioactivity in the presence (---) or absence (——) of vWF.

factor XIIIa concentration tested, 80% of the vWF was covalently bound to fibrin. Analysis of the material in fibrin–vWF clots showed that the presence of vWF had a small effect of the rate of the fibrin gel formation (Fig 3B). At 2 minutes, 58% of the fibrinogen in the test system was in the clot in the sample without vWF, and 48% was in the clot in the sample with vWF. At 15 minutes, the values were nearly the same (87% without vWF and 85% with vWF); by 2 hours, there was no difference in the fibrin content of the two clotting systems.

Composition of the fibrin–vWF gels was analyzed by reduced SDS gel electrophoresis. Figure 4 shows the radioactivity profile of vWF and the fibrin polypeptide chains for fibrin formed in the presence or absence of vWF. At the earliest time point (2 minutes) fibrin γ chain content was decreased and γ-γ dimers were prominent. Fibrin α chains were also somewhat decreased, and small oligomers of α chains were visible, as well as some high-mol-wt α polymer. At this point, a small amount of vWF-α chain dimers and some larger components were seen, but there was no vWF in the α polymer fraction. In this assay, monomeric vWF, derived from vWF polypeptides that had been disulfide-bonded to other polypeptide chains that had become crosslinked to fibrin, was also observed. A principal effect of vWF appeared to be to decrease the rate of high-mol-wt α polymer formation. Similar results were observed at 15 minutes, at which time some vWF had appeared in the α polymer fraction and the sample without vWF still contained more α polymer than the sample with vWF. By 4 hours, most of the vWF had become crosslinked into the α polymer fraction, with residual vWF monomers and vWF-α chain dimers remaining.

Competition between vWF and fibronectin for crosslinking to α chains was investigated in a purified test system in which 94% of the fibronectin and 88% of the vWF was crosslinked when each was added separately to the clotting mixture. When both were present in the test system, identical amounts of both vWF and fibronectin were crosslinked to fibrin, indicating that there was no competition for α chain sites.

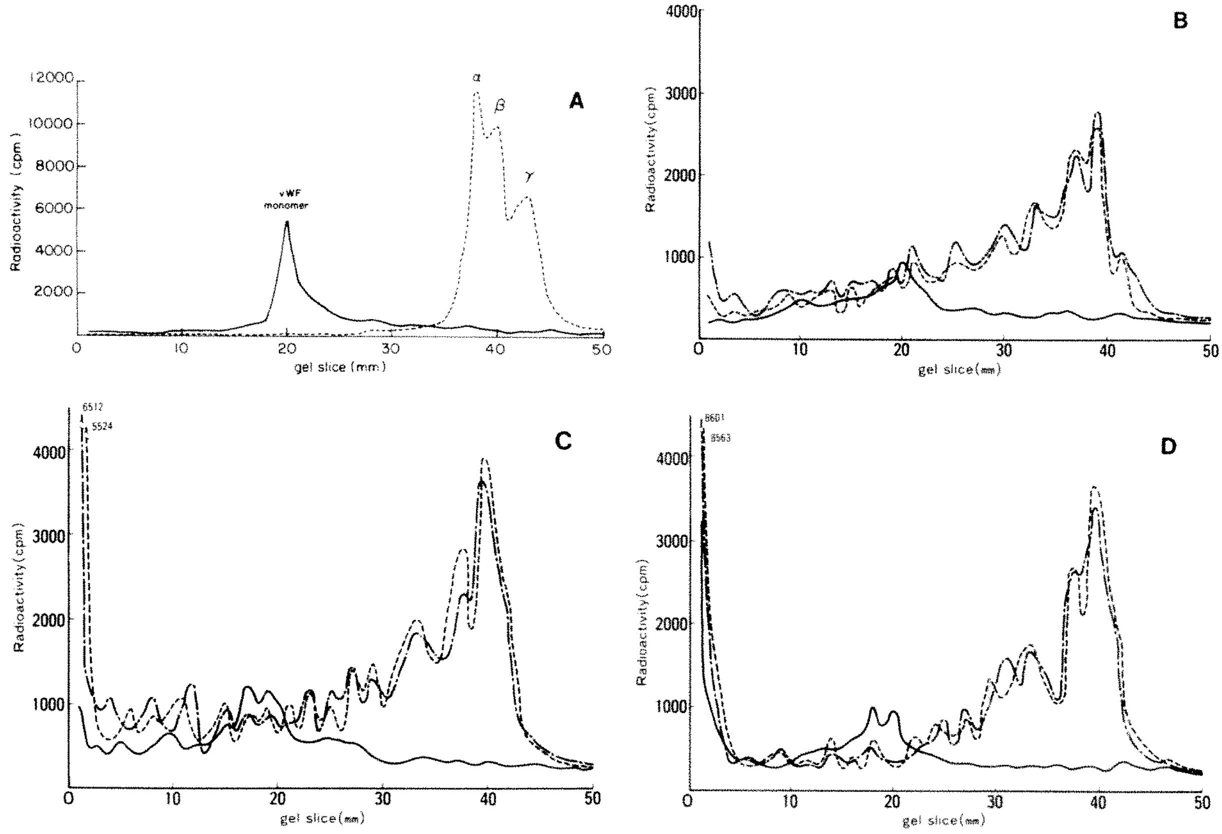

Fig 4. Effect of vWF on fibrin crosslinking. Samples were prepared as follows: (A) ^{131}I-fibrinogen and ^{125}I-vWF were mixed together to show the control proteins; (B through D) samples were prepared in three ways—^{131}I-fibrinogen + vWD, fibrinogen + ^{125}I-vWF, and ^{131}I-fibrinogen. In each case with vWF, the molar ratio was 30 fibrinogen:1 vWF. In all cases, the samples were clotted with thrombin, $CaCl_2$, and 5 U/mL of factor XIII. At intervals, the crosslinking reaction was stopped; samples were analyzed by sodium dodecyl sulfate gel electrophoresis, followed by measurement of radioactivity in the gel segments as in Fig 2B to determine the crosslinking patterns of fibrin without vWF (-·-), fibrin with vWF (----), and vWF (——). (A) Control gel showing starting fibrinogen and vWF: no reaction with factor XIII. (B) Reaction time, 2 minutes. Several fibrin peaks can be identified; from right to left, these represent γ chain (mol wt 48,000), β chain (mol wt 54,000), α chain (mol wt 64,000), γ dimer (~mol wt 96,000), and α dimer (~mol wt 139,000), α trimer (~mol wt 215,000 to 231,000). Larger oligomers cannot be identified with certainty. High-mol-wt α polymer is indicated by the rising counts at the left side (top) of the gel. (C) Reaction time, 15 minutes; (D) reaction time, 240 minutes. In C and D, free γ chain has disappeared, but other lower mol wt peaks are the same as in B.

Table 1. Incorporation of vWF Into Fibrin During Clotting of Normal Plasma and Hemophilia A Plasma

	Normal	Hemophilia A
Recalcification time	10 min	69 min
Plasma fibrinogen	7.3 μmol/L	7.9 μmol/L
Fibrin in gel	92%	76%
Plasma vWF	0.06 μmol/L	0.08 μmol/L
vWF in gel	3%	20%

Covalent crosslinking of vWF to fibrin was also investigated in a plasma test system. Table 1 shows that upon recalcification of normal plasma little vWF became incorporated into the fibrin gel. However, recalcification of plasma from a patient with severe hemophilia A resulted in incorporation of 20% of the plasma vWF. The same results were also obtained with factor IX-deficient plasma, indicating that this was not a special property of hemophilic vWF. In these studies, plasma levels of fibrinogen, vWF, and factor XIII were normal, and the only significant differences were the long recalcification times and increased fibrin-vWF crosslinking in the deficient plasmas. This observation was further investigated by adjusting normal and factor VIII-deficient plasmas to the same clotting times and measuring vWF incorporation in the fibrin gels (Fig 5). Normal plasma was clotted with 10 mmol/L of $CaCl_2$ and dilutions of hirudin and deficient plasma with $CaCl_2$ and dilutions of thrombin so that clotting times of the two plasmas were approximately equal. The results showed that when the clotting times were the same, the amount of vWF incorporation into fibrin was also the same. The distribution of vWF in the plasma clots was examined on reduced SDS gels. In the normal plasma clot (recalcification time 10 minutes), it can be seen that very little vWF was incorporated (Fig 6A). The expected distribution of crosslinked fibrin components was also seen, with predominantly α chain, γ-γ dimer, and high-mol-wt α polymer. Smaller amounts of α monomer and α chain oligomers were also observed. With the factor VIII-deficient clots (recalcification time 69 minutes) vWF was found in the α polymer fraction (Fig 6B). Monomeric vWF and vWF-α chain dimer could also be clearly identified on the gels. The content of α polymer was decreased, and the amount of intermediate α chain oligomers was increased. Thus, in factor VIII-deficient plasma or in normal plasma in which the clotting time was prolonged, vWF was covalently bound to fibrin in a manner identical to that observed with purified reagents.

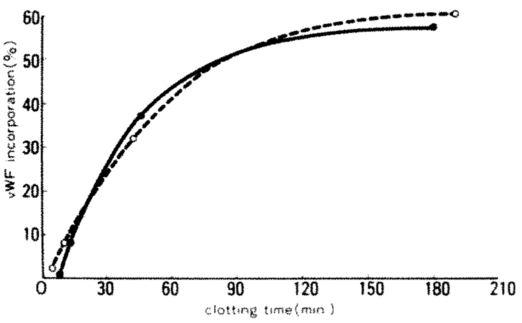

Fig 5. Covalent crosslinking of vWF to fibrin in normal plasma (——) and factor VIII deficient plasma (----) as a function of clotting time. Clotting times were adjusted by adding hirudin to normal plasma and thrombin to deficient plasma. Clots were allowed to form for 3 hours at 37 °C before analysis.

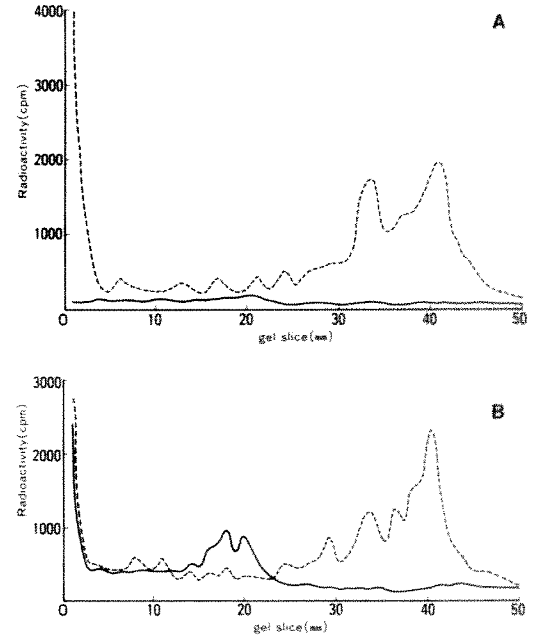

Fig 6. Crosslinking patterns of fibrin and vWF in (A) normal plasma, and (B) factor VIII-deficient plasma. Trace amounts of ^{125}I-vWF and ^{131}I-fibrinogen were added to each plasma and clotting was initiated by addition of 10 mmol/L of $CaCl_2$. Clots were allowed to form for 3 hours at 37 °C before analysis. Fibrin (---); vWF (——).

DISCUSSION

The product of the crosslinking reaction catalyzed by factor XIIIa is ϵ-(γ-glutamyl)lysine, which results from formation of a peptide bond between the γ-carboxamide of peptide-bound glutamine and the ϵ-amino of lysine, thus forming a covalent bridge which links two proteins together.[27] Factor XIIIa appears to have significant substrate specificity requirements, and only certain glutamine and lysine residues in certain proteins are suitable substrates. These include the crosslinking of fibrin γ chains to form γ-γ dimers and fibrin α chains to high-mol-wt α polymers.[28,29] Fibronectin and α_2-antiplasmin are crosslinked to fibrin α chains,[30-32] and fibronectin can also crosslink to collagen.[33] The studies described here show clearly that both monomeric and polymeric forms of von Willebrand factor also act as substrates for factor XIII activity by providing appropriate glutamine residues for the crosslinking reaction. Crosslinking of vWF to fibrin α chains can occur readily during clotting.

vWF is present in normal plasma as a series of disulfide-bonded polymers that range in molecular size from 800,000 to >12,000,000.[34] In these studies, several forms were used: purified vWF monomers, purified polymers with the size distribution of plasma vWF, and the array of polymers distributed in plasma. Purified monomers and polymers, as well as plasma vWF, could participate in crosslinking; but only monomers could clearly crosslink to other monomers to form vWF dimers, trimers, and higher polymers (Fig 2A). Disulfide-bonded polymers of vWF were not crosslinked by factor XIIIa to form larger aggregates (Fig 2B). However, vWF polymers were readily crosslinked to fibrin. In these experiments, it was not ascertained whether the size distribution of polymers which crosslinked to fibrin was random or whether a particular fraction was preferentially involved.

Crosslinking of fibrin γ chains to form γ-γ dimer occurs at the protofibril stage of fibrin gelation.[35] It is rapid, occurs with very low factor XIIIa levels, and is difficult to inhibit.[27] This may be partly because fibrin monomer units are already aligned in the protofibril so that the γ chain crosslinking sites are properly oriented. In contrast, crosslinking of fibrin α chains is slow and highly dependent on the factor XIIIa concentration, with much of the α polymer being formed after gelation.[36] Crosslinking of both fibronectin and vWF to α chains is similar to α polymer formation. In purified test systems with fibronectin, ~50% is crosslinked to fibrin before visible gelation occurs when the thrombin concentration is in the range of 0.05 to 2.0 U/mL, and the remaining fibronectin crosslinking occurs much more slowly.[37] Similar results were observed with vWF-fibrin crosslinking in purified systems, in which prolonged incubation resulted in increased vWF crosslinking after the gel had formed (Fig 4). However, in the plasma system, increased incorporation of vWF polymers was observed when the gelation time was increased (Fig 5), but it was not observed with prolonged incubation after the gel had formed relatively rapidly (Fig 6). The requirement for a long gelation time in plasma may explain why vWF may not be observed as a substrate for factor XIIIa when plasma is clotted rapidly.[38]

Participation of vWF as a substrate for crosslinking by factor XIIIa is similar to fibronectin crosslinking. Each protein can crosslink to itself only in the reduced forms. Both proteins crosslink to the α chain of fibrin and, in so doing, decrease the rate of α polymer formation. However, crosslinking of one protein to α chain does not inhibit the crosslinking of the other. This is similar to the previously described observation that fibronectin and α_2-antiplasmin do not compete for crosslinking sites in α chains of fibrin.[39] It is known that α chains can form at least three covalent crosslinks per polypeptide chain, but this number is not normally obtained in α polymer formation. It appears that some of the lysine crosslinking sites are more readily occupied by glutamines in other proteins than by other α chains.[40] It is unlikely that more than one other protein would be crosslinked to a given α chain because the concentration of α chains in the gel is so much greater than that of other proteins. The principal glutamine crosslinking sites in fibronectin[41] and α_2-antiplasmin[42] are located very close to the amino-termini, well suited for their interdigitation within the α-polymer. A crosslinking site in vWF has not yet been localized.

The observation that vWF polymer formation crosslink to fibrin during plasma clotting (Figs 5 and 6) may explain the decreased level of serum vWF sometimes observed when clotting of hemophilia plasma was prolonged. This was previously ascribed to an alteration in serum vWF.[13] Other investigators have also observed decreased α polymer formation in plasma clots of patients on coumadin or with severe factor VIII deficiency.[43] We interpret the data presented here, as well as the observations of others, to indicate that when the clotting of plasma is prolonged, other proteins, including vWF, can be covalently bound to fibrin α chains by factor XIIIa, with a concomitant decrease in the rate of α polymer formation. It seems likely that this reaction might also be expected to occur in vivo when thrombin generation is limited.

Although the significance of vWF crosslinking to fibrin is unclear, several possibilities can be considered.One possibility involves the contact sites of the fibrin clot with vascular subendothelium. We have obtained evidence that vWF can also crosslink to collagen.[44] Hence, the possibility exists for vWF to function as a covalently held bridge between the fibrin clot and collagen in the subendothelium. The large molecular size of the vWF polymer would be appropriate for such a function. vWF is relatively resistant to plasmin digestion,[45] and its presence in the fibrin clot might also increase resistance of the clot to plasmin degradation. Recent evidence has also been presented concerning the function of vWF in mediating the interaction between platelets and polymerizing fibrin.[46] Covalent crosslinking of a small fraction of vWF to fibrin as it polymerizes would stabilize this interaction. Thrombospondin is also a substrate for factor XIIIa,[47] and it too could have a role in crosslinking reactions involving vWF on the platelet surface.

ACKNOWLEDGMENT

We wish to thank Drs K. Fukutake, M. Fujimaki, and S. Ikematsu, Department of Clinical Pathology, Tokyo Medical College, for their support and cooperation. We also wish to thank Behringwerke A.G. for the Fibrogammin used in these studies.

Inhibition of Prostaglandin E_2 Restores Defective Lymphocyte Proliferation and Cell-Mediated Lympholysis in Recipients After Allogeneic Marrow Grafting

By Hans-G. Klingemann, Mang-So Tsoi, and Rainer Storb

Prostaglandins are said to influence T and B cell function by inhibiting the generation of interleukin 2 (IL 2) and the formation of suppressor lymphocytes. After bone marrow transplantation, patients usually have a profound immunodeficiency that persists in recipients with chronic graft-*v*-host disease (GVHD) and generally resolves in long-term survivors without GVHD. In vitro tests of lymphocyte function such as allogeneic mixed lymphocyte culture (MLC) and cell-mediated lympholysis (CML) have been shown to be impaired in many patients. We postulated that prostaglandin E_2 (PGE_2) plays a role in the impaired in vitro tests. To test this hypothesis, we studied in vitro tests in the presence of PGE_2 antagonists, indomethacin, and anti-PGE_2 antiserum with cells from 22 short-term patients (<100 days postgrafting) and 32 long-term survivors with or without GVHD. Results show that blockade of PGE_2 release by indomethacin and anti-PGE_2 significantly ($P < .01$) enhanced the MLC (+67%) and the CML responses (+10.5%) of cells from long-term survivors with chronic GVHD but not from those of long-term, stable recipients. No enhancement of MLC and CML activity was observed with cells from donors of long-term recipients. In patients shortly after marrow grafting, enhancement in the MLC was not significant. However, CML activity in this patient group was significantly increased (+12.5% in recipients with no GVHD, 8.5% in those with acute GVHD, $P < .01$). Indomethacin also suppressed the activity of nonspecific suppressor cells in patients with chronic GVHD. When cells from patients with chronic GVHD were treated with recombinant IL 2 and IL 2 combined with indomethacin, it was possible to get an additional augmentation of lymphocyte proliferation after the addition of indomethacin to IL 2–treated cultures. Thus it is very likely that PGE_2 inhibits T lymphocyte proliferation, not exclusively by inhibition of IL2 production or activity. We conclude that PGE_2, among other factors, may play a role in the pathogenesis of the immunodeficiency after transplantation. PGE_2 does not act primarily by interfering with IL 2 but presumably by inducing a suppressorlike activity.

EXPERIMENTS in a number of species have demonstrated that some immune functions are inhibited by prostaglandin E_2 (PGE_2)[1] such as lymphocyte proliferation,[2,3] activation of cytotoxic lymphocytes,[4,5] cell-mediated lympholysis (CML), and B cell proliferation.[6] In murine and human models, monocytes produce sufficient amounts of PGE_2 to mediate this inhibitory effect.[7,8] There are several explanations for the way in which PGE_2 exerts its inhibitory activity. Evidence is growing that PGE_2 is bound to a functional subset of human T cells that leads to their activation as suppressor cells.[3,9-12] Other data suggest that PGE_2 interferes with interleukin 2 (IL 2) production or activity[13,14] and/or that it reduces Ia expression on monocytes.[15]

Many patients after bone marrow transplantation (BMT) have a profound immunodeficiency related to impaired function of both B and T cells. This immunologic defect may be severe and life threatening, is seen in all patients within the first few months of transplantation, and persists in long-term survivors who have chronic graft-*v*-host disease (GVHD).[16-20] In marrow recipients, reduced lymphocyte proliferation can be restored by exogenous IL 2.[21] The same is true for the diminished CML in patients with acute GVHD, but not for those with chronic GVHD.[22]

It was the aim of this investigation to evaluate whether PGE_2 contributes to the impaired mixed lymphocyte culture (MLC) reactivity and CML of cells from patients after BMT. The results obtained show that in vitro blocking of PGE_2 action by two distinct inhibitors improves lymphocyte proliferation and CML activity in cells from marrow graft recipients. In addition, cells from patients with chronic GVHD were treated with IL 2 or indomethacin, or both. The augmenting effect on allogeneic lymphocyte proliferation by each substance was additive. This observation makes it very likely that PGE_2 inhibits T lymphocyte proliferation not only by inhibition of IL 2 production or activity. Our results point to an indomethacin-sensitive suppressor cell that inhibits lymphocyte proliferation and whose effects cannot be overcome by exogenous IL 2 alone.

MATERIAL AND METHODS

Patients and donors: Marrow transplantation. Cells from 61 allogeneic marrow recipients (8 with aplastic anemia, 38 with acute myelogenous leukemia, 11 with acute lymphoblastic leukemia, and 4 with non-Hodgkin's lymphoma) were studied 22 to 948 days after allogeneic marrow transplantation. The patients' ages ranged from 2 to 49 years; 34 were male and 27 female. Details of the transplantation procedures have been described previously.[23] Patients with aplastic anemia were conditioned for grafting with cyclophosphamide, 50 mg/kg, on each of four successive days. Those with malignancies were conditioned for grafting with a combination of cyclophosphamide, 60 mg/kg, on each of two successive days and total-body irradiation. Evidence for marrow engraftment was obtained by monitoring the peripheral blood count, marrow cellularity, and cytogenetic markers. Patients were divided into four groups based on the time of testing and the presence or absence of GVHD (first figure gives the number of patients tested in MLC; the figure in parentheses refers to the number of patients tested for CML): 11 (10) short-term patients with acute GVHD tested between 22 and 94 days after BMT, 16 (11) short-term patients without GVHD tested

between 33 and 100 days after BMT, 22 (11) long-term patients with chronic GVHD tested between 294 and 858 days, and 12 (7) long-term patients without chronic GVHD tested between 312 and 948 days after BMT. In all long-term recipients, cells from marrow donors were tested simultaneously with those of their respective recipients to serve as normal syngeneic controls. The protocol for this study was subject to initial approval and subsequent annual reviews by the Human Subjects Review Committee of the Fred Hutchinson Cancer Research Center and the University of Washington. All participants in the study signed committee-approved consent forms.

Reagents. Indomethacin (Sigma Chemical Co, St Louis, catalog No. 1-7378) was dissolved in 95% ethanol at 4 mg/mL and diluted to 20 μg/mL in RPMI 1640 medium (GIBCO, Grand Island, NY) before use. It was determined that addition of ethanol at concentrations equal to those present in the dissolved drug had no detectable effect on our cultures. Indomethacin was used in concentrations of 0.01 μg/mL (3×10^{-8} mol/L) to 10 μg/mL (3×10^{-5} mol/L). Since 1 μg/mL gave optimal enhancement under our experimental conditions as determined by a dose-response curve, we chose this as the final concentration for all experiments added on day 0 to the cultures. Rabbit anti-PGE$_2$ was purchased from Sigma (No. P 6765) and dissolved in phosphate-buffered saline at 5 mg/mL. Lyophilized PGE$_2$ (5Z, 11X, 13E, 15S)-11,15-dihydroxy-9-oxoprosta-5,13-dien-1-oicacid purchased from Sigma (No. P 5640) was initially dissolved in 95% ethanol at a concentration of 0.1 mg/mL (2.8×10^{-4} mol/L) and was used at a final concentration of 10^{-8} mol/L, in RPMI 1640 medium. The final concentration of ethanol in the cultures was <0.1%.

Recombinant IL 2 (lectin free) was purchased from Amgen Biologicals (Thousand Oaks, Calif, No. 01010) and dissolved in 10 μmol/L Tris-buffered saline, pH 8. Twenty units were added to each culture.

Purification of lymphocytes and culture media. Peripheral blood mononuclear cells (PBMC) were obtained from heparinized whole blood by density gradient centrifugation using lymphocyte separation medium (Bionetics) as described.[24] The mononuclear cells were suspended in RPMI 1640 supplemented with 2 mmol/ L-glutamine (GIBCO), 25 mmol/L HEPES buffer (GIBCO), 1% penicillin-streptomycin solution (GIBCO), and 20% heat-inactivated pooled human male serum. All cultures were incubated at 37 °C in humidified 5% CO$_2$ in an air atmosphere.

Mixed lymphocyte cultures. Unidirectional allogeneic MLC were performed in quadruplicate of U-bottomed plates (Costar, Cambridge, Mass) with 1×10^5 responder and an equal number of irradiated (16 Gy) stimulator cells in 0.2 mL RPMI 1640 culture medium. After incubation for six days, cultures were pulsed with 2 μCi of ^{3}H-thymidine (New England Nuclear, Boston) and incubated for six hours. The cultures were harvested and processed with an automated microplate harvester (Cambridge Technology, Cambridge, Mass), and incorporation of radioactivity was measured in a liquid scintillation counter and expressed as the mean counts per minute per quadruplicate cultures ± SD. The variation among microcultures did not exceed 15%. To exclude any direct effect on the responding or stimulator cells, controls were run with responding and stimulator cells using media alone or alternatively with indomethacin, anti-PGE$_2$, or IL 2. Response to allogeneic stimulator cells after addition of indomethacin, anti-PGE$_2$, or IL 2 was expressed as the net counts per minute of cells with the additive minus counts per minute of cells without the additive.

CML assay. To use as few cells as possible from most patients, the indirect CML assay was carried out by a micromethod according to Zarling et al[25] with slight modifications. MLC were set up as described with 2×10^5 responder and stimulator cells per well. Target PBMC (5×10^6/2 mL) from the same donor as the stimulator cells were prepared at the same time as the stimulator and were incubated under the same conditions as the MLC. On day 6 of MLC, the target cells were concentrated in 0.1 mL of heat-inactivated fetal calf serum and were labeled with 300 μCi of ^{51}Cr (Na$_2$ ^{51}CrO$_4$, New England Nuclear) for 60 minutes at 37 °C. After incubation and washing, they were resuspended at 1×10^5/mL in RPMI 1640 with 5% fetal calf serum. An aliquot (0.1 mL) of the supernatant was removed from each MLC culture, and an equal volume of the labeled target cells (1×10^4 cells) was added to each culture, making the ratio of effector to target cells 10:1. After centrifugation (140 g for five minutes) the plates were incubated for six hours at 37 °C in a humidified 5% CO$_2$ incubator.

An aliquot of supernatant was then harvested from each culture and its radioactivity determined in a gamma counter. The percentage of ^{51}Cr release was calculated from the formula: (experimental release − autologous release) × 100/(maximum release − autologous release).

Maximum release values were obtained by adding 0.15 mL of 0.1% Nonidet P40 to 0.1 mL of target cells. Controls with autologous stimulator cells were performed with medium, indomethacin, or anti-PGE$_2$, which were added at the initiation of the assay. In each experiment three different dilutions (5:1, 10:1, 50:1) of effector cells were tested to determine whether a log linear relationship existed between the ratio of effector cells to target cells and the amount of ^{51}Cr release. Since we never observed decreased results at different effector-target ratios (E:T) ratios that did not appear at the 10:1 E:T ratio, only the results obtained with this ratio are presented.

Nonspecific suppressor cell assay. PBMC of the recipient (chimera cells of donor marrow origin) were cocultured with lymphocytes obtained from the marrow donor and irradiated third-party stimulator cells in a mixed lymphocyte reaction. Control cultures consisted of chimera cells alone responding to third-party stimulators and donor cells alone responding to the same stimulators. The percent suppression in any single test was calculated according to the formula: $1 - [DuP/(DuD + PuP)/2] \times 100$ = percent suppression (D, donor PBMC; P, patient PBMC; U, unrelated irradiated lymphocytes). A positive percentage indicated the degree of suppression of donor response by patient cells. A percentage greater than 25% was used as a guideline for detecting cases with suppression.[23]

Statistical methods. The Wilcoxon two-sided signed rank test was applied to paired responses of patient PBMC before and after in vitro treatment. Values for allogeneic induced lymphocyte proliferation from patients were considered significantly different from normal if an individual patient value fell <2 SD below the mean for the control group. Comparisons between groups were done with Student's *t* test.

RESULTS

Improvement of allogeneic MLC of cells from marrow recipients by exogenous indomethacin. Allogeneic lymphocyte proliferation was tested in the MLC with cells from four groups of marrow recipients. Reactivity of cells from patients was compared with that of cells from their respective donors. The results are presented in Table 1 and Fig 1. Cells from short-term patients and patients with chronic GVHD showed a markedly reduced ^{3}H-thymidine uptake as compared with long-term patients without GVHD or healthy donors. Exogenous indomethacin increased the response rate in cells of patients with chronic GVHD ($P < .01$) and in long-term stable recipients ($P < .05$). There was no significant beneficial effect in the cells of patients shortly after transplantation, regardless of whether GVHD was present. There was also no correlation between immunosuppressive medication after marrow grafting (ie, cyclosporine, metho-

trexate, antithymocyte globulin) and impaired MLC responses.

Since indomethacin is not a specific PG synthetase inhibitor, we compared its effect with that obtained with an anti-PGE$_2$ antiserum using cells from eight patients with chronic GVHD. Results in Fig 2 illustrate that ^{3}H-thymidine incorporation in cells from these patients was enhanced by anti-PGE$_2$ in a manner similar to that seen with indomethacin.

Restoration of CML activity with indomethacin in recipients shortly after grafting and in patients with chronic GVHD. CML activity was diminished with cells from all patient groups regardless of the time after transplantation. Results are summarized in Table 2 and Fig 3. Before exogenous indomethacin was added, CML activity was lowest in recipients with acute and chronic GVHD. The addition of indomethacin improved CML by 8.6% and 10.6%, respectively, but normal activity could be achieved only in patients with chronic GVHD and in short-term patients with no GVHD, but not in recipients with acute GVHD. CML activity was also enhanced by indomethacin in long-term patients with no GVHD (+6.3%) and in healthy controls (+4.4%). This improvement was statistically not significant (Wilcoxon signed rank test). As in the MLC, The antiserum against PGE$_2$ was equally effective in enhancing CML activity compared with indomethacin (Fig 2).

Effect of the addition of PGE$_2$. PGE$_2$ (10^{-8} mol/L) suppressed proliferation of cells from healthy individuals in the MLC as well as their activity in the CML (range of suppression, 35% to 68% in both tests, results of eight controls). When indomethacin (1 μg/mL) was added to the cultures together with PGE$_2$, PGE$_2$-induced suppression was not reversed (results not shown).

Additive effects of IL 2 and indomethacin on the allogeneic MLC of patients with chronic GVHD. PBMC of nine patients with chronic GVHD were stimulated with irradiated allogeneic cells in the presence and absence of IL 2, indomethacin, and IL 2 plus indomethacin (Table 3). The addition of IL 2 to PBMC cultures from patients augmented the proliferation by a mean of 60% (range, 7% to 131%). The addition of indomethacin to the same cultures augmented the MLC by a mean of 68% (range, 27% to 156%). However, adding the combination of IL 2 and indomethacin increased proliferation by a mean of 172% (range, 21% to 534%). This increase was statistically significant ($P < .01$) if compared with the increases observed with each single agent.

The percent increase of cpm was calculated as follows: (average cpm of indomethacin-treated cells/average cpm of control cultures) − 1.0 × 100.

Generation of nonspecific suppressor cells is decreased after indomethacin. We tested the PBMC of patients with chronic GVHD for nonspecific suppressor cells and found in four recipients nonspecific suppressor activity greater than 25%. Exogenous indomethacin decreased suppression in all of these cases significantly ($P < .001$). In three of these patients suppressor activity was reduced to ≤25% (Fig 4).

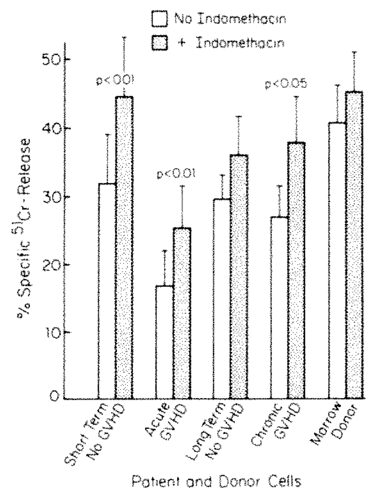

Fig 3. CML with cells from marrow recipients and donors in the presence and absence of indomethacin. Significance was assessed by the Wilcoxon two-sided signed rank test.

DISCUSSION

To understand the underlying causes of immunodeficiency commonly seen in patients early after allogeneic BMT and in long-term survivors with chronic GVHD, we had earlier analyzed various cellular immune functions during different stages of T cell activation of marrow recipients and found that (1) their monocytes usually had normal function[26,27] and could produce IL 1[28]; (2) their T cells were immunologically defective[18,20,28] and were deficient in IL 2 production[21]; and

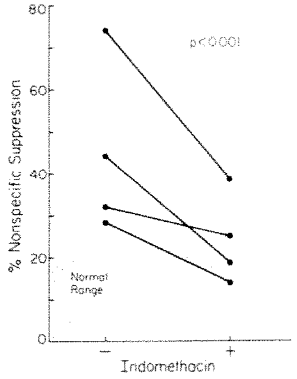

Fig 4. Effect of indomethacin on the activity of nonspecific suppressor cells. Four patients with chronic GVHD demonstrated suppression greater than 25%. In all four cases, suppressor activity was reduced to ≤25%.

(3) exogenous IL 2 restored the T cell CML activity of most recipients early after grafting, but not of patients with chronic GVHD.[22] In addition, nonspecific suppressor cells were found in some recipients, with chronic GVHD[24] thought to contribute to the depressed T cell immunity and subsequently to a higher incidence of late infections.[29] These findings and the reports from others showing that human IL 2 production was regulated by PGE_2[13,14] and that PGE_2 might be involved in suppressor T cell induction[9,11,12,30,31] prompted us to investigate the role of PGE_2 in the immunodeficiency after marrow grafting.

We made use of the findings of several laboratories that PGE_2 was able to inhibit human lymphocyte proliferation[1-4,6] and that blocking of PGE_2 effects by indomethacin or antiserum against PGE_2 could restore the in vitro immune response.[32-34] We were able to demonstrate that the impaired MLC and CML activity with cells from many recipients after marrow transplantation, especially in long-term patients with chronic GVHD, was significantly improved by exogenous indomethacin and also by an anti-PGE_2 antiserum. Our demonstration that a specific anti-PGE_2 serum could mimic the effect of indomethacin suggests that PGE_2, rather than other prostaglandins produced by adherent cells, is the main immunosuppressive factor. These findings suggest a role for PGE_2 in the severe immunodeficiency seen in patients after marrow grafting.

What are the mechanisms of PGE_2-mediated immunosuppression? Some authors believe that PGE_2 directly suppresses human lymphocyte proliferation by interfering with both the production of IL 2 and IL 2–dependent proliferation.[13,14] Others[9,11,32] claim that PGE_2 suppressed lymphocyte responses indirectly by activation of a suppressor cell. Our present data showing that the activity of nonspecific suppressor cells in patients with chronic GVHD can be significantly inhibited by indomethacin points to PGE_2 as a possible inducer of the suppressor activity. Furthermore, Fisher et al[10] recently demonstrated PGE_2 receptors on human suppressor lymphocytes.

As to the cause of increased PGE_2 effects, two explanations are possible: an enhanced sensitivity of grafted lymphocytes to normal PGE_2 levels or an increased production of PGE_2. As shown by Lapp et al,[35] PGE_2 synthesis by mouse macrophages is induced during GVHD reaction. But they also observed that the response to indomethacin was abrogated about 15 to 20 days after GVHD induction. The fact that the augmentation of the allogeneic MLC with indomethacin did not reach significance in our patients with acute GVHD might be explained by this observation, since most of our patients had their disease for more than 2 weeks before being tested.

In addition to our observation with indomethacin only, it was possible to enhance the allogeneic MLC by combining indomethacin and IL 2. The response was superior to the effect of either agent alone. A recent paper by Chouaib et al[36] confirmed this observation. Exogenous IL 2 restored PGE_2-induced inhibition of T cell proliferation only partially. They showed that PGE_2 downregulates the expression of the transferrin receptor, which has been correlated with cell proliferation in normal lymphocytes.

PGE_2 is known to increase the intracellular concentration of adenosine 3'5'-cyclic monophosphate (cAMP).[37] By testing other drugs that enhance intracellular cAMP levels and reduce transferrin receptor expression, Chouaib et al[36] concluded that cAMP might be the mediator of the inhibitory effect of PGE_2 on lymphocyte proliferation. Our observation of a reduction in in vitro activity of nonspecific suppressor cells by indomethacin and the fact that it was possible to get an additional augmentation of lymphocyte proliferation after the addition of indomethacin to IL 2–treated cultures suggest the existence of an indomethacin-sensitive suppressor cell whose effect can apparently not be overcome by IL 2 alone. A similar additive effect of indomethacin and IL 2 was observed in cancer patients whose PBMC were stimulated by phytohemagglutinin.[34,38]

Recent observations in the mouse model showed no increase in the incidence of GVHD by administration of IL 2 in vivo while simultaneously improving the defective immunologic responsiveness of recipient mice.[39] Based on our in vitro studies in man, it might be possible that a combination of IL 2 and indomethacin is superior compared with IL 2 alone in correcting a defective immune response after experimental marrow grafting without aggravating GVHD.

ACKNOWLEDGMENT

We gratefully acknowledge the expert technical assistance of S. Dobbs and E. Santos. We are indebted to the medical, nursing, and ward clerk staffs of the Division of Oncology for their cooperation in this study. The authors wish to thank Dr L.G. Lum for his helpful advice and careful reading.

Cytomegalovirus-Specific Lymphocyte Proliferation and In Vitro Cytomegalovirus IgG Synthesis for Diagnosis of Cytomegalovirus Infections After Bone Marrow Transplantation

By Per Ljungman, Berit Lönnqvist, Gösta Gahrton, Olle Ringdén, and Britta Wahren

With new techniques 19 bone marrow transplant (BMT) recipients were monitored for lymphocyte proliferation and specific IgG production in vitro by cytomegalovirus (CMV) antigen in solid phase. Twelve patients got a reactivated CMV infection as defined by virus isolation or serum IgG conversion. Lymphocyte proliferation and in vitro IgG production responses were significantly stronger in these 12 patients than in seven without ongoing CMV infection ($P = .02$). CMV infection was indicated by the lymphocyte responses at a mean of 45 days after BMT as against a mean of 79 days that passed before CMV growth in culture was detected ($P < .05$). Lymphocyte proliferation and in vitro IgG production may thus be used as tools for diagnosis and for monitoring of CMV infections in BMT recipients.

© 1986 by Grune & Stratton, Inc.

CYTOMEGALOVIRUS (CMV) infection is a major problem after allogeneic bone marrow transplantation (BMT).[1] Despite antiviral therapy mortality in CMV, pneumonitis exceeds 80%.[2,3] Treatment with a new antiviral drug, phosphonoformic acid (foscarnet), is reportedly effective in BMT patients with encephalitis and pancytopenia and in renal transplant recipients with pneumonitis.[4,5] In a few cases it has also been effective in BMT recipients with CMV pneumonitis.[6] An early diagnosis of CMV infection is therefore important in these patients. CMV isolations frequently give positive results, but it may take several weeks for a cytopathic effect to appear in culture. Demonstration of early antigens after short-term culture is feasible[7,8] but in our experience may be less sensitive than the classic isolation procedure. Specific IgG and IgM determinations in serum are of minor value for the diagnosis of CMV infections, since in reactivated disease of immunocompromised patients antibody increases often appear late or not at all.[9]

The question whether immunity to herpesviruses is transferred from the donor or persists in the recipient has been addressed. Wahren et al found that the humoral reactivity to viral antigens may either be transferred with donor B cells at BMT or persist among host cells for varying times after BMT.[10] Although engraftment may occur, usually neither long-term transfer nor persistence of herpesvirus-reactive T lymphocytes is seen.[9,11] The cells that mediate the lymphocyte proliferation response to CMV antigen are mainly T cells[12] of the helper/inducer (T4) phenotype (ref 13 and our own unpublished results). Lymphocyte proliferation to all types of antigens, including herpesvirus antigens, is strongly depressed early after BMT.[9,14] Together, these findings indicate that a CMV reactivation should be regarded as a new primary infection by the immune system of the BMT recipient.[14]

New techniques have been developed for measuring specific lymphocyte proliferation to CMV antigen and specific lymphocyte IgG production in vitro.[15] The lymphocytes are exposed to the CMV antigen in solid phase. These techniques were found to be specific and sensitive indicators of reactivity to CMV in healthy individuals. They were found to be useful indicators of CMV infection in BMT recipients.

MATERIALS AND METHODS

Patients. The BMT procedure has been described.[16,17] Out of 20 patients, there were three instances of aplastic anemia, one T cell defect with hypogammaglobulinemia, five acute nonlymphoblastic leukemias (one in first remission, four in partial remission), six acute lymphoblastic leukemias (two in first and four in second remission), one multiple myeloma, and four chronic granulocytic leukemias (two in first chronic phase, one in accelerated phase, and one in second chronic phase (Table 1). All received grafts from HLA-identical, MLC-nonreactive sibling donors. The study was approved by the ethical committee at Huddinge Hospital, and informed consent was obtained from all patients before grafting. The four patients with nonmalignant disease received cyclosporine as prophylaxis against acute graft-*v*-host disease (GVHD). The patients with malignant diseases were randomized between cyclosporine ($n = 10$) and methotrexate ($n = 6$). Cyclosporine therapy was started on day 1 with 5.0 mg/kg/d intravenously (IV) followed by 12.5 mg/kg/d orally in two divided doses when oral medication was tolerated. Acute GVHD was graded according to Thomas et al.[16] Chronic GVHD was defined according to Shulman et al and Schubert et al[18,19] and was verified by biopsies.

Eleven cases in which donor and/or recipient were CMV seropositive before BMT were considered to run a high risk of CMV infection developing.[9] They were included in the randomized study for either prophylactic treatment with CMV-hyperimmune plasma or no such treatment. Lymphocytes from these 16 patients were studied weekly from the time when the white cell count reached 1.0×10^9 cells/L after the initial hypoplasia until 12 weeks after BMT. Thereafter, tests were performed monthly. Four recipients who were seronegative and had seronegative donors were regarded as a low-risk group for CMV infection developing.[9] All these patients received CMV antibody-negative blood products.

Thirteen out of the 16 patients in the high-risk group and all four in the low-risk group survived the first 3 months after BMT. One patient died of a leukemic relapse on day 37 after BMT, and two died of a CMV pneumonitis on day 70 and 75 respectively. After 3 months, one patient died on day 108 of septicemia and one on day 120 of a pneumonitis caused by *Pneumocystis carinii*. Acute GVHD of grade III to IV developed in five patients, grade II in five, and grade I in five. All patients with acute GVHD were treated with prednisone, with an initial dose of 2 mg/kg bodyweight, and seven

*ATG, prednisone, and methylprednisolone.

†Prednisone.

patients received high-dose methylprednisolone and/or antithymocyte globulin in addition (ATG, Table 1).

Diagnosis of CMV disease. The diagnosis of a CMV infection was made by virus isolation on human lung (HL) fibroblasts. Samples for CMV isolation were taken weekly from urine and blood cells during the first 12 weeks after BMT and later at least monthly. CMV isolation attempts were also made on bone marrow and on material obtained from bronchoscopies and liver biopsies and on autopsy material. CMV IgG and IgM antibodies in serum were determined weekly by enzyme-linked immunosorbent assay (ELISA).[20] The following serologic criteria were considered significant for a CMV infection: specific IgM production, CMV IgG seroconversion, or a fivefold specific IgG increase. In patients receiving CMV-hyperimmune plasma transfusions, these were considered in the evaluation of the IgG titer rises.

Viral antigens. CMV nucleocapsid and CMV membrane antigens were prepared from HL cells infected with CMV Ad 169 as described.[20,21] Control antigens were similarly prepared from uninfected HL cells. Lymphocyte proliferation was studied using CMV nucleocapsid antigen because the lymphocytes of healthy CMV-seropositive persons responded better to CMV nucleocapsid than to CMV membrane antigen.[15] CMV membrane antigen was used for stimulation of in vitro CMV IgG production because IgG synthesis in vitro was better with the membrane than with the nucleocapsid antigen. For control purposes, lymphocyte assays were made with herpes simplex virus (HSV) antigens[21,22] and varicella zoster virus (VZV) antigens.[21,23] These tests were sometimes precluded by a lack of cells.

Proliferation technique. Coating of 96-well microplates (Nunc Immunoplate I, Nunc, Roskilde, Denmark) was performed overnight at room temperature with 100-μL volumes (1 μg viral protein) of CMV nucleocapsid antigen. Before use, the plates were washed three times with saline containing 0.05% Tween 20. Patient lymphocytes were prepared from heparinized blood by centrifugation on Lymphoprep (Nyegaard & Co, Oslo). After washing, the lymphocytes were suspended in RPMI 1640 supplemented with 10% CMV antibody–negative AB+ human serum, and 1.5×10^5 cells in 200 μL of suspension were dispersed into two antigen-coated plates. After three and five days, 1 μCi of 3H-thymidine was added. Twenty four hours later the cells were harvested (Titertec, Skatron, Lierbyen, Norway), and the activity was measured in a scintillation counter. Each test was performed in triplicate. A net cpm was calculated as the mean cpm from stimulated cultures minus the mean cpm from control antigen-stimulated cultures. The control antigen was nonstimulatory for the lymphocytes (mean cpm ≤ 800, Fig 1). A net cpm of >1,000 is considered specific for DNA synthesis and indicates that the patient has had a CMV infection.[11,15] A net cpm rise of <10,000 or a more than tenfold rise in the net cpm from a previous test was considered specific for ongoing reactivated CMV infection.

Lymphocyte-produced CMV IgG and IgM determination by ELISA. Microplates were coated with 100-μL volumes (1 μg of viral protein) of CMV membrane antigen.[17] The lymphocytes were suspended in RPMI 1640 with 20% fetal calf serum, and 2.0×10^5 cells were dispersed in duplicate into the antigen-coated plates. After 48 hours the plates were washed three times with saline containing

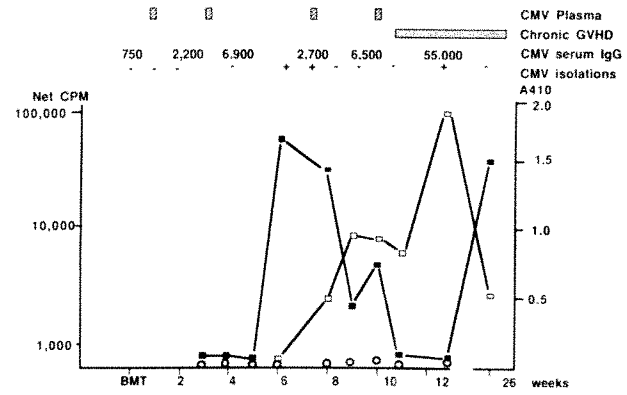

Fig 1. Lymphocyte proliferation to CMV antigen (■), control antigen (O), and specific in vitro IgG production (□) responses after BMT in patient L089 (Table 1) with CMV infection compared with CMV isolation and total specific IgG titers. Loss of responses was followed by a new episode of CMV excretion and a second rise of the proliferation response.

0.05% Tween 20. After washing, 100 μL of alkaline phosphatase-conjugated goat antihuman IgG (Sigma Chemical Co, St Louis) or antihuman IgM (Orion Diagnostika, Helsinki, Finland) was added and the plate incubated for two hours at 37 °C. Then, 100 μL of the substrate *p*-nitrophenyl phosphate (1 mg/mL, Sigma) was added at room temperature, and 30 minutes later the reaction was terminated with 2.5 mol/L NaOH. The absorbance (A) at 410 nm was measured in a Dynatech MR 600 (Arlington, Va). The tests were performed in duplicate. Net absorbance was calculated as the mean A 410 value from CMV-stimulated lymphocytes minus the mean A 410 value of cultures stimulated with control antigen. An A 410 rise of ≥0.4 (0.4 is twice the background level of each assay) was considered to be specific for CMV IgG production.[15,20]

RESULTS

CMV infections. CMV infection developed in 12 of the 16 high-risk patients. Fifteen were confirmed by CMV isolations. Three of them also had serum CMV IgG titer rises. One patient had a CMV IgG seroconversion. None had detectable (titer <50) serum CMV IgM. CMV pneumonitis developed in three patients and two died. The third patient was treated with phosphonoformic acid (foscarnet) and survived the pneumonitis but later died of septicemia. Five patients with CMV infection had pancytopenia and/or fever. Three of the high-risk patients had neither clinical signs of CMV disease nor virologic evidence of a CMV infection. One patient was not evaluable because virus isolations were not adequately sampled. No CMV infection developed in any of the low-risk patients.

Lymphocyte proliferation responses. CMV-specific lymphocyte proliferation responses developed in ten of 12 patients with CMV infections (minimum values for previous tests and maximum cpm values for each patient are shown in Table 1). Eight of these patients had a net cpm of more than 10,000 and all had a more than tenfold rise in the net cpm compared with a previous test (Table 1, Fig 1). None of the seven patients without CMV infection had a net cpm of more than 3,400 (Table 1, Fig 2). Table 2 shows a significant difference in the mean responses between the two patient groups (*P* = .02 by the two-tailed Mann-Whitney U test).

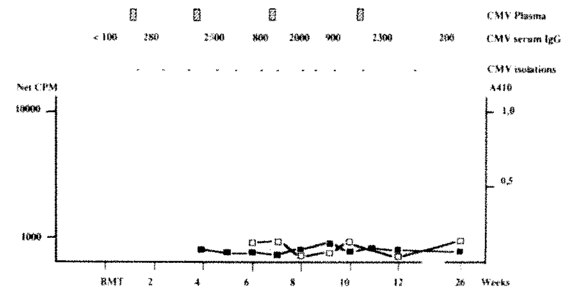

Fig 2. Lymphocyte proliferation (■) and IgG production (□) responses in a patient (L091) without CMV infection (seropositive donor, seronegative recipient).

The proliferation responses rapidly rose to a peak value, and during follow-up the responses usually diminished (Fig 1). In three patients, lymphocyte proliferation responses before treatment with ATG (net cpm of 148,000, 48,000, and 8,000, respectively) became deeply depressed after this treatment (net cpm <1,000). In three out of four patients in whom chronic GVHD developed, a strong CMV-specific proliferation response at the diagnosis of CMV infection was lost during follow-up.

The strong proliferation responses occurred specifically in response to infection. In every case where we found a net cpm of >10,000 after BMT against any herpesvirus antigen (CMV, HSV, VZV), a virus reactivation was confirmed by other means.

Two patients had a herpesvirus antigen-stimulated net cpm of between 5,000 and 10,000 the first weeks after marrow take. This was followed by a rapid decrease. One of these patients (L100) is presented in Fig 3. CMV was later isolated, and a second rise to a net cpm of 12,000 was seen before the patient died of CMV pneumonitis. This patient was CMV-seropositive before BMT and had a seropositive donor. Either the transfer of CMV-reactive lymphocytes from the donor or the persistence of the patient's own lymphocytes would explain the stimulation response directly after BMT. The second patient (L97) was seronegative for HSV before BMT and had an HSV-seropositive donor. This patient had a positive lymphocyte response with HSV antigen without signs of HSV infection during the first 2 months

Table 2. Mean Maximum CMV-Specific Lymphocyte Proliferation and Mean Specific Antibody Production In Vitro for BMT Recipients With and Without CMV Infection

Patients	Mean Net cpm (Range)*	Mean Net A 410 (Range)*
With CMV infection (n = 12)	31,400 (400-148,000)	0.9 (0.2-2.0)
Without CMV infection (n = 7)	900 (200-1,400)	0.2 (0.0-1.0)†

**P* = .02, Mann-Whitney U test, two tailed.

†One patient died early in relapse.

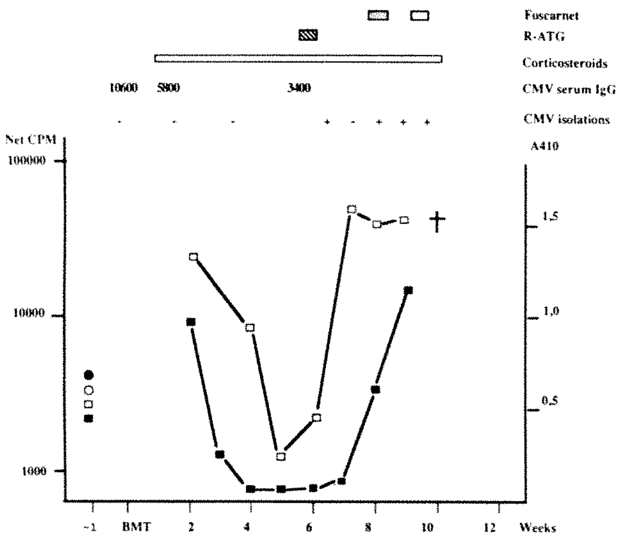

Fig 3. Lymphocyte proliferation (■, patient; ●, donor) and IgG production (□, patient; ○, donor) responses in patient (L100) who died of CMV pneumonitis. In this patient transfer or persistence of CMV-reactive lymphocytes may have occurred (first peak of specific proliferation and IgG responses).

after BMT. The response was lost later. This indicates a transfer of reactive cells from donor to recipient.

CMV-specific antibody production in vitro. Specific IgG production by lymphocytes could be detected (net A 410 > 0.4) in nine of 12 patients with CMV infection. Eight had at least a fivefold rise in the amount of CMV IgG produced as judged by the absorbance levels. In eight of these patients, at least two successive positive tests were found. In six of the seven patients without CMV infection, no IgG production could be detected (A ≤ 0.4; $P < .05$ by the two-tailed Mann-Whitney U test). One patient, who died early in relapse, had an A 410 of 1.0 that later decreased rapidly. No CMV IgG rises were seen in patients without a CMV reactivation. No lymphocyte-produced CMV-specific IgM was detected in any of the patients.

In six patients an initial IgG response to CMV antigen was seen, followed by a decrease (Fig 3). Five of these recipients were seropositive before BMT with seropositive donors. CMV infection developed in these patients, and in three of them, later, strong CMV IgG production was seen. Both transfer and persistence of IgG-producing lymphocytes are feasible in these cases.

CMV-specific lymphocyte proliferation and CMV IgG production in vitro correlated with the diagnosis of CMV infection. Lymphocyte proliferation responses and in vitro IgG production both quickly indicated a CMV infection after BMT (Table 3). When the two methods were combined, 11 of 12 CMV infections were detected. The 12th patient had severe acute GVHD and was treated with methylprednisolone and ATG. He later died of a CMV pneumonitis. A positive CMV-specific lymphocyte proliferation and/or an in vitro IgG production response developed significantly sooner than growth of CMV in culture or a CMV IgG titer rise in serum ($P < .05$ by Wilcoxon's rank sum test). In six of seven patients, either positive CMV-specific lymphocyte proliferation or IgG production was found before either CMV isolation or a serum antibody increase. In the seventh patient, a CMV IgG increase in serum was the first sign of CMV infection.

Table 3. Day for Diagnosis Post-BMT of CMV Infection by Virus Isolation and Serum CMV IgG Compared With the Day for Rise of CMV-Specific Proliferation Response (Net cpm >10,000 or a Tenfold Net cpm Rise) and/or In Vitro Production of CMV IgG (A 410 > 0.4)

Test for Diagnosis of CMV Infection	No. of Patients		Mean No. of Days After BMT (Range)
	Positive	Negative	
Samples taken			
CMV isolation	11	1	45 (33-76)
Serology (>5-fold IgG rise)	4	8	87 (31-122)
Lymphocyte proliferation	10	2	39 (17-72)
In vitro IgG production	9	3	53 (20-80)
Diagnosis obtained			
CMV isolation	11	1	79 (61-112)
Serology + CMV isolation*	12	0	80 (31-123)
Lymphocyte proliferation + in vitro IgG production*	11	1	45 (19-78)

*$P < .05$, Wilcoxon's rank sum test.

DISCUSSION

The magnitude of CMV-specific lymphocyte proliferation responses was found to differ significantly between patients with and without CMV infection. There was also a difference in the in vitro CMV IgG production response. Responses seen early after BMT may reflect transfer or persistence of reactive lymphocytes, but such early responses usually diminished during the first weeks. Patients with proven reactivated CMV infections had secondary strong rises of in vitro lymphocyte responses to CMV. A strong rise in the lymphocyte proliferation response and/or a rise in the production of CMV-specific IgG in vitro may therefore be used as adequate diagnostic signs of a CMV infection.

We used unfractionated lymphocyte populations to minimize the loss of cells with specific functions, especially those of antigen presentation. This also has the advantage that the T cell and B cell responses can be analyzed simultaneously.

It is difficult to define exactly the time after BMT at which a CMV reactivation starts. We therefore calculated the number of days from BMT until the first positive assay for CMV was obtained with each of the methods. With the criteria used (a net cpm rise to >10,000, a tenfold rise in net cpm, or a net A 410 rise of >.4), the time to diagnosis of a CMV infection was determined by the time at which first positive CMV isolation was obtained. Considering the time required for CMV replication in culture and the in vitro lymphocyte tests, the detection of CMV reactivation was achieved significantly sooner with the lymphocyte proliferation/IgG production tests.

We noted that CMV-specific lymphocyte proliferation responses reached an early peak and often diminished later. The reason for this is unknown. It may have to do with a decreased activity of T4 cells. CMV infection has been associated with a depressed T4/T8 ratio,[24] and in four of seven patients with CMV infection, a low T4/T8 ratio was found (data not shown). Patients who received ATG treatment rapidly acquired a depressed lymphocyte proliferation response to CMV. A decreased activity of T4 cells may be mediated by suppression, for instance, induced by CMV. In two of three patients in this study in whom chronic GVHD has thus far developed, the lymphocyte proliferation responses were lost while CMV excretion has continued. This is in agreement with our earlier results showing that lost CMV-specific lymphocyte proliferation responses were more common in patients with chronic GVHD.[9] Chronic GVHD is associated with immunoincompetence,[25,26] and nonspecific suppressor cells have been found in patients with chronic GVHD (for a review see Tsoi et al, ref 27).

In summary, we have found that increased CMV-specific lymphocyte proliferation and in vitro IgG production to CMV antigen may be used as tools for the early diagnosis of CMV infection after BMT.

Expression of p53 in Human Leukemia and Lymphoma

By M. Prokocimer, M. Shaklai, H. Ben Bassat, D. Wolf, N. Goldfinger, and V. Rotter

Analysis of fresh human tumors have indicated that patients with B type lymphoproliferative diseases and the majority of patients with acute lymphoblastic leukemia (ALL) express elevated levels of p53 production. It is suggested that in these human malignancies, p53 may provide a novel tool for monitoring cancer activity. Conversely, p53 is not expressed in acute myeloid leukemias, myeloproliferative diseases, or myeloid leukemic cell lines. Analysis of the p53 gene structure indicated the existence of similar patterns of p53 restriction fragments in producer and nonproducer cells, which suggests that the p53 gene is not altered in the latter. However, in one case of acute promyelocytic leukemia (APL), we have observed a rearrangement in the p53 gene. Karyotype analysis has indicated that these APL cells do not contain the typical 15;17 translocation. In other APL patients who exhibit a 15;17 translocation, we found no genomic changes of the p53, suggesting that the p53 gene, which was recently mapped to the short arm of chromosome 17 in the human, is not structurally related to the typical chromosomal break point found in the long arm of chromosome 17 of APL patients.

© 1986 by Grune & Stratton, Inc.

THE CELLULAR encoded protein p53 is overproduced in cancer cells. Accentuated concentrations of this protein have been detected in a large number of transformed cell lines[1] and in primary tumors in mice.[2] It was found in a variety of tissue types, including sarcoma and leukemia cells of several species.[3-7]

A direct role for p53 in the process of carcinogenesis was suggested by experiments that showed that expression of the p53 gene can immortalize cells and that the p53 gene can replace the *myc* oncogene in a *myc-ras* immortalization/transformation assay.[8-10] In addition, we found that the introduction of a functional p53 gene into p53 nonproducer[11] L12 Ab-MuLv–transformed cells that have a rearranged p53 gene changed their phenotype from cells that induce regressor tumors into cells that induce the appearance of lethal tumors. These and other experiments suggest a correlation between expression of p53 in tumor cells and the capacity of the latter to exhibit a fully transformed phenotype.

Recently we and others became interested in evaluating the possible role of the p53 oncogene in human neoplastic growth and differentiation. We were especially interested in studying the expression and gene structure of p53 in human leukemia-lymphoma cells in comparison with analogous normal tissues. A study of the hematologic malignant diseases was attractive because we have recently mapped the p53 gene to the short arm of chromosome 17.[12] Gain or loss of the whole chromosome 17 or parts of it has been a frequent finding in these malignancies.[13] We were in particular interested in studying patients with acute promyelocytic leukemia (APL), since a reciprocal translocation involving chromosomes 15 and 17 at bands q22 and q21, respectively, is a characteristic abnormality in APL.[14] The study group consisted of patients with (1) acute leukemias, acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL); (2) myeloproliferative diseases, chronic myeloid leukemia (CML) with Philadelphia chromosome–positive cells (ph'+), myelofibrosis (MF), myeloid metaplasia (MM), and polycythemia vera (PV); (3) chronic lymphocytic leukemia (CLL); and (4) lymphoma in leukemic phase. We extended our study to include a large number of established human lymphoma-leukemia cell lines. The availability of a cloned human p53 cDNA[15] and specific anti-p53 monoclonal antibodies[16-18] permitted us to survey p53 expression and its gene structure in human lymphoma-leukemia cells.

MATERIALS AND METHODS

Cell lines. The following human leukemia-lymphoma cell lines were tested: ALL cell lines including Reh, Km-3, Peer, Amsalem, Molt-4, Nalm-6, Nalm-1; Burkitt's lymphoma cell lines including Ramos, Bjab, Bjab-B958, Ra-B958, Raji, Daudi; Myeloid cell lines[19] including the K-562 erythroleukemic cell line,[20] HL-60 promyelocytic cell line,[21] and the Dekabuto myeloid cell line (Ben Bassat, unpublished observations). In addition we tested SV80, a human transformed fibroblastic cell line expressing the SV40 DNA tumor virus,[22] and a normal human permanent B cell line established from peripheral blood lymphocytes infected by Epstein-Barr virus (EBV) (B958) (Ben-Bassat, unpublished observations).

All cell lines were grown in RPMI 1640 enriched with 10% heat-inactivated fetal calf serum (Biolab, Jerusalem, Israel) and 2×10^{-5} mol/L β-mercaptoethanol. Hybridoma cell lines PAb421,[16] PAb122,[17] and RA3-2C2[18] were grown in RPMI 1640 medium enriched with 20% heat-inactivated fetal calf serum supplemented with 20 mmol/L L-glutamine and 20 mmol/L sodium pyruvate.

Patients. Samples of heparinized venous blood and bone marrow cells were obtained from patients and normal healthy volunteers who gave informed consent. The samples were collected at the time of diagnosis or at relapse from patients with ALL, AML, CML ph+', MF, lymphoma in leukemic phase, and CLL. Diagnoses were made by using standard clinical, morphologic, cytochemical, and immunologic criteria. Eighty percent or more of the cells in each of these cases was malignant by the aforementioned criteria.

Antibodies. Monoclonal anti-p53 antibodies were obtained from the established hybridoma cell lines PAb421,[16] PAb122,[17] and RA3-2C2.[18] Monoclonal antibodies were obtained from either supernatants of the hybridoma cell lines or ascitic fluid of syngeneic mice

injected intraperitoneally (IP) with the hybridoma cell lines. Antibodies were purified and concentrated by binding to Sepharose–protein A columns (Sigma Chemical Co, St Louis).

Synthesis of p53 protein. A quantity of 1×10^7 cells of each individual cell line, sample of bone marrow, peripheral blood mononuclear cells, or one plate of fibroblasts at the logarithmic stage of growth were washed several times in phosphate-buffered saline (PBS), resuspended in 1.5 mL Dulbecco's modified Eagle's medium without methionine, and enriched with 10% dialyzed heat-inactivated fetal calf serum and 250 μCi ^{35}S-methionine (purchased from Amersham Corp, Buckinghamshire, England). Cells were incubated for one hour at 37 °C, washed in PBS, and extracted into 2 mL of lysis buffer (10 mmol/L Na_2HPO_4-NaH_2PO_4, pH 7.5, 100 mmol/L NaCl, 1% Titron X-100, 0.5% sodium deoxycholate, 0.1% sodium dodecylsulfate) at 4 °C. Labeled cell lysates were precleared by repeated absorption on *Staphylococcus aureus* and nonimmune serum. Equal amounts of radioactive protein were immunoprecipitated with specific antibodies. Antigen-antibody complexes were collected by *S aureus*.[23] Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was performed according to Laemmli.[24]

Southern blot analysis. Genomic DNA was prepared from individual cell lines and fresh leukemia-lymphoma cells. Cells were washed twice with PBS, resuspended in lysis buffer (0.5% SDS, 50 mmol/L Tris-HCl, 5 mmol/L EDTA, pH 7.5) and 0.2 mg/mL proteinase K (Boehringer Mannheim, FRG), and incubated for 14 hours at 37 °C. The solution was extracted twice with an equal volume of phenol and twice with equal volumes of chloroform/isoamylalcohol 24/1. The DNA solution was adjusted to a final concentration of 0.3 mmol/L Na-acetate, and 2 vol of cold ethanol was added. The DNA precipitate formed at room temperature was washed twice with 80% ethanol and resuspended in 10 mmol/L Tris-HCl and 1 mmol/L EDTA (pH 7.5). Aliquots of 10 μg DNA digested with *Eco*RI and *Hind*III were electrophoresed on 0.8% agarose gel, blotted onto nitrocellulose filter,[25] and hybridized to nick-translated[26] p53 DNA probes.[15,27]

RESULTS

Expression of p53 protein in established human cell lines. Using the human specific anti-p53 monoclonal antibodies PAb421 and PAb122, we screened a large number of human lymphoma-leukemia cell lines for expression of p53. Figure 1 illustrates an example of several human cell lysates immunoprecipitated with PAb421. As shown in this figure, human cell lines express more than one p53 protein species. Some lines, like SV-80–transformed fibroblasts and the Reh-ALL cell lines, synthesize two physically distinct proteins, whereas others express either the lower or the upper p53 protein species (Molt-4 and Nalm-6, respectively). Table 1, which summarizes results with all the human lines we have studied, indicates that all T and B leukemia cell lines as well as a normal human permanent B cell line infected by EBV B958 expressed the p53 protein evaluated by immunoprecipitation with specific anti-p53 monoclonal antibodies. These findings are in agreement with the detection of the p53 protein in human cell lines previously documented.[5,6] p53 synthesis, however, was not detected in the following human myeloid leukemic cell lines: HL-60,[21] K-562 (Fig 1), and Dekabuto (not shown).

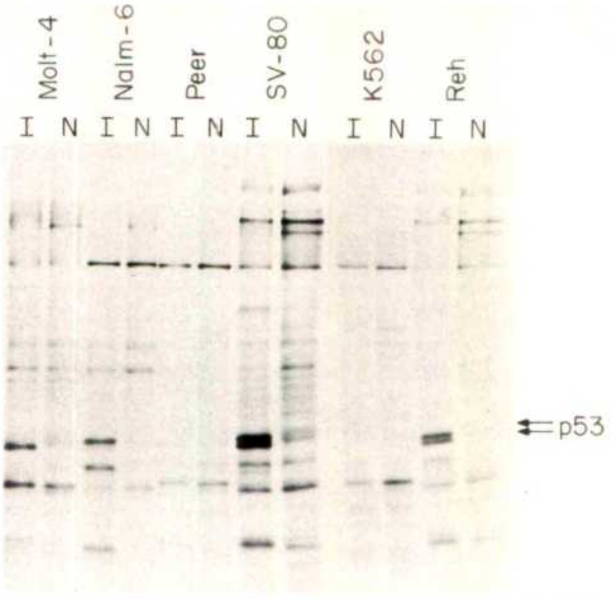

Fig 1. Expression of the p53 protein in human established cell lines. Equal amounts of ^{35}S-methionine–labeled cell lysates were immunoprecipitated with nonimmune serum (N) or PAb421 anti-p53 monoclonal antibodies (I). The dried gel was autoradiographed for 1 week.

Analysis of the p53 gene in the p53 producer and unproducer cell lines tested by Southern blotting using a human specific cDNA probe, p53-H-13,[15] indicated a similar pattern of restriction fragments digested with EcoRI or double digested with *Eco*RI and *Hind*III in all cell lines. The HL-60 cells are the only exception; they were found to contain a major deletion in the p53 gene (Fig 2).[27]

Expression of p53 in fresh leukemia-lymphoma cells. Fresh human leukemia-lymphoma cells were tested for expression of the p53 protein using human-specific anti-p53 monoclonal antibodies, PAb421,[16] and a control of

(—), p53 was undetectable by immunoprecipitation.

RA3-2C2, mouse-specific anti-p53 (Fig 3).[18] p53 expression was detected in all of the following patients: (1) B-CLL, (2) B lymphoma in leukemic phase, and (3) in five out of six patients with ALL (Table 2). Overall, ALL and lymphoma samples displayed more intense signals than did the CLL samples. In the latter, prolonged exposures of 3 to 4 weeks' duration were usually required for visualization of the signals. As in human cell lines, fresh tumors express more than one p53 species. Indeed, we observed several tumors that synthesize a single p53 protein, whereas in others, two and occasionally three physically distinct proteins were detected.

Evaluation of p53 expression in nontransformed human cells indicated the absence of detectable levels of p53 in thymocytes, in peripheral blood lymphocytes, and in bone marrow progenitor cells. p53 protein synthesis, however, was detected in fetal cord blood obtained immediately after delivery.

p53 synthesis was not detected in patients with AML, CML (ph'+), MF, or PV (Table 2). Prolonged exposures of autoradiograms for longer than four weeks, did not yield a p53 signal in these samples.

Southern blot analysis of genomic DNA isolated from these samples was performed using the p53 human-specific cDNA probe (p53-H-13).[15] The results illustrated in Fig 4 showed a similar pattern of restriction fragments in producer and nonproducer cells, suggesting that the p53 gene analyzed

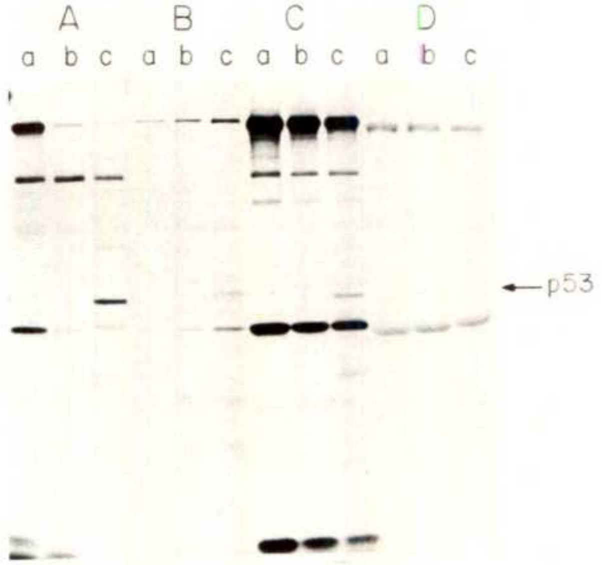

Fig 3. **Expression of p53 protein in human fresh leukemia-lymphoma cells. Patients with the following diseases were studied: lymphoma (A), CLL (B) ALL (C), and AML (D). Equal amounts of ^{35}S-methionine–labeled cell lysates were immunoprecipitated with either nonimmune serum (a), RA3-2C2 mouse-specific anti-p53 (b), or PAb421 human-specific anti-p53 (c). The dried gel was autoradiographed for 4 weeks.**

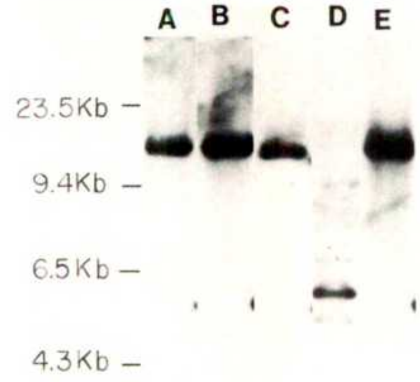

Fig 5. Southern blot analysis of the p53 gene in patients with APL. Equal amounts of DNA obtained from individual patients were digested with *EcoRI*, separated by electrophoresis, and hybridized with the human-specific cDNA probe p53-H13. Karyotype analysis of patients A, B, C, and E exhibited the classic 15;17 translocation. Karyotype analyses were performed on G-banded preparations as previously described.[32,33]

under these resolution conditions is intact in p53 nonproducer fresh tumor cells.

Analysis of the p53 gene in leukemic cells of patients with APL. Previously we found that most of the p53 gene in the HL-60 promyelocytic cell line was deleted.[27] In these cells only one chromosome 17 was detected.[29] The fact that the human p53 gene was shown to map to chromosome 17 as well as the observation of Larson et al showing a consistent 15q22 to 17q21.1 chromosomal translocation in patients with APL[14] prompted us to extend our survey and analyze p53 expression in APL patients. To that end five patients with APL were analyzed. The criteria for the diagnosis of APL were as described previously.[31] All patients either had disseminated intravascular coagulation on presentation, or the syndrome developed after initiation of chemotherapy. Cytogenetic evaluation of bone marrow was performed in all the patients. Four patients had the classic translocation 15;17, and one had a normal karyotype. Results shown in Fig 5 indicated that four patients who had the classic translocation seem to present an intact p53 gene as evaluated by Southern blotting. A typical pattern of restriction fragments was obtained with these patients (Fig 5, lanes a, b, c, and e). However, in the single patient diagnosed as having APL exhibiting a normal chromosomal karyotype with no 15;17 translocation, a rearrangement of the p53 was observed (Fig 5, lane d).

DISCUSSION

Recently we and others became interested in studying p53 expression in human cancers. These studies have been directed toward the question of whether the p53 gene is overexpressed in human malignancies.

Our study has focused on evaluation of the p53 protein expression and its gene structure in the fresh human lymphoma-leukemia cells and in established lymphoma-leukemia cell lines. Using the human-specific anti-p53 monoclonal antibodies PAb421, PAb122, and a cloned human p53 cDNA as a probe, we screened a variety of human primary tumors. We have observed that most of the malignant tissues studied expressed an elevated level of p53 synthesis compared with analogous normal tissues. All Burkitt's lymphoma and ALL (T and B) human cell lines as well as all patients with B-CLL, B lymphoma in leukemic phase, and a majority of patients with ALL expressed elevated levels of p53 protein synthesis. This suggests that p53 overexpression is an authentic phenomenon rather than a tissue culture artifact.

We found that fresh ALL, B lymphomas generally displayed an increase in signal intensity compared with the majority of CLL cells, suggesting that the rate of synthesis of p53 in leukemic cells derived from patients with ALL lymphomas is increased over that in CLL cells. Since p53 is a nuclear-associated protein that may be involved in the control of DNA replication, it is possible that p53 is more frequently synthesized in the more rapidly proliferating acute leukemia or lymphoma cells than in the less-proliferating CLL cells. Analysis of the p53 protein in fresh tumors has indicated the presence of several p53 protein species varying in their molecular size. As in human cell lines, some synthesize a single p53 protein, whereas others synthesize two or even three physically distinct proteins. This differential expression of several p53 species by the single human p53 gene could be controlled by an alternative splicing mechanism (manuscript in preparation).

Previously we observed that the p53 gene of HL-60 cells, a promyelocytic leukemic cell line, was significantly altered. Most of the p53 gene was deleted in these cells and therefore failed to produce the p53 protein.[27] In this study we further observed the lack of a detectable level of p53 protein in other myeloid cell lines such as the K-562 (erythroleukemic cell line derived from the pleural effusion of a patient with CML in blastic crisis) and Dekabuto cell lines. These findings are in agreement with the results reported by Miller et al.[34] It should be noted, however, that p53 is expressed in the Nalm-1 cell line.[35] This line was established from the peripheral blood of a patient who was in blastic crisis of ph^1 CML. It was derived from the lymphoid type of CML blasts. Lack of p53 expression was also evident in fresh samples obtained from patients with AML and myeloproliferative diseases such as CML, MF, and PV. These observations suggest that this gene may play a role in early hematopoietic differentiation. The p53 gene may be completely shut off through gene inactivation in myeloid differentiation. Alternatively, lack of the p53 protein in myeloid leukemias might suggest the existence of a different transformation mechanism in these malignancies.

Southern blot analysis of p53 producer and most of the nonproducer cell lines or fresh tumors studied here indicate that the p53 gene seems intact. Under the present resolution conditions, we have observed similar patterns of p53 restriction fragments in p53 producer and nonproducer cells.

In the group of APL patients, we observed one of the five in which the p53 gene was rearranged. In that particular case no 15;17 translocation typical for APL was evident. In the other four cases of APL in which a typical translocation of the long arm of chromosome 17 to chromosome 15 was found, no modifications in the p53 gene were observed. This strongly suggests that the 15;17 translocation break point and the p53 gene are not structurally related. This is further emphasized by the fact that the p53 gene was mapped to the short arm of chromosome 17, which is usually not altered by the typical 15;17 q22-21.1 translocation.[12] Taken together, it seems that the assumption that p53 has a critical involvement in the transformation of normal myeloid cells into leukemic cells put forth by LeBeau et al[30] seems to be unlikely. These findings are not consistent with our previous observation of a major deletion of the p53 gene in the HL-60 promyelocytic cell line.[27] We would like to speculate that the rearrangement of the p53 gene in HL-60 cells was caused by a change in the karyotype involving the loss of chromosome 17 during the continuous passage of these cells in culture. Alternatively, it is possible that APL patients exhibit at a low frequency an additional rearrangement occurring in the short arm of chromosome 17. Therefore, the rearrangement in one APL patient as well as the deletion in the p53 gene in HL-60 cells may be an authentic observation.

In summary, the p53 protein is expressed in B-type lymphoproliferative diseases and in the majority of ALL patients as well as in lymphoid cell lines of both T and B origin, including Nalm-1 cells. In these malignancies, p53 may provide a novel tool for monitoring the activity of malignancies. Conversely, p53 is not expressed in AML, myeloproliferative diseases, and myeloid leukemic cell lines. Understanding of these variations in p53 expression in the different tumor cells may provide some insight into the biologic roles of p53 in normal and malignant cells.

ACKNOWLEDGMENT

The authors wish to thank Dr W.H. Schubach, Oncology Division, State University of New York at Stony Brook, for providing the DNA of a patient with APL (see Fig 5, lane e).

Marrow Transplantation for Severe Aplastic Anemia: Methotrexate Alone Compared With a Combination of Methotrexate and Cyclosporine for Prevention of Acute Graft-Versus-Host Disease

By R. Storb, H.J. Deeg, V. Farewell, K. Doney, F. Appelbaum, P. Beatty, W. Bensinger, C.D. Buckner, R. Clift, J. Hansen, R. Hill, G. Longton, L. Lum, P. Martin, R. McGuffin, J. Sanders, J. Singer, P. Stewart, K. Sullivan, R. Witherspoon, and E.D. Thomas

Forty-six patients with severe aplastic anemia (median age, 23 years) were treated with high-dose cyclophosphamide followed by infusion of marrow from an HLA-identical family member. To evaluate postgrafting prophylaxis for graft-*v*-host disease (GVHD), they were entered into a prospective randomized trial comparing the effect of a combination of methotrexate and cyclosporine (n = 22) to that of methotrexate alone (n = 24). Forty-four of the forty-six patients had evidence of sustained marrow engraftment. Only one patient in each of the two study groups showed graft rejection. A significant reduction in the cumulative incidence of grades II to IV acute GVHD was seen in patients given methotrexate/cyclosporine (18%) compared with those given methotrexate alone (53%) (*P* = .012). In three patients given methotrexate alone, grade III developed, and in six, grade IV acute GVHD developed, compared with none given methotrexate/cyclosporine. Eighteen of the 22 patients given methotrexate/cyclosporine and 15 of the 24 given methotrexate alone are alive between 5.5 and 44.5 months (median, 18 months), with actuarial survival rates at 2 years of 82% and 60%, respectively (*P* = .062). The incidence of fatal infections was higher in patients given methotrexate alone, whereas there are as yet no significant differences in the incidence of chronic GVHD. We conclude that methotrexate/cyclosporine treatment resulted in a significant decrease in the incidence and severity of acute GVHD in patients who received transplants for severe aplastic anemia and thus an improvement in survival.

© 1986 by Grune & Stratton, Inc.

TRANSPLANTATION of marrow from HLA-identical siblings has been used successfully to treat patients with severe aplastic anemia.[1-6] Acute graft-*v*-host disease (GVHD) has remained a serious problem adversely affecting survival. Studies in experimental animals have shown that administration of immunosuppressive agents after grafting can be effective in obviating GVHD. Methotrexate, cyclosporine, and cyclophosphamide have been frequently used for prevention of GVHD in humans. Three randomized prospective comparisons of methotrexate and cyclosporine in patients with leukemia have shown either no or only marginal reduction in the incidence of acute GVHD in patients given cyclosporine, without significant improvement in survival.[7-9] Two recent studies in dogs given DLA-nonidentical unrelated and DLA-haploidentical littermate marrow grafts have demonstrated a significant decrease in the incidence of acute GVHD, with improvement in survival when animals were given a short course of methotrexate combined with cyclosporine compared with either methotrexate or cyclosporine alone.[10,11] We have carried out a prospective randomized trial comparing the usefulness of the combination of methotrexate and cyclosporine to that of methotrexate alone in patients with severe aplastic anemia given HLA-identical sibling marrow grafts. We report this experience with 46 patients whose cases have been followed for 5½ months to 3¾ years after transplantation.

MATERIALS AND METHODS

From Dec 14, 1981, to March 14, 1985, 46 patients were entered into the study. Patient characteristics are shown in Table 1. There were no significant differences between the two study groups as regards patient characteristics. Marrow donors and recipients were HLA-A and -B identical siblings whose cells were mutually nonreactive in mixed leukocyte culture in 45 cases, and one patient given methotrexate/cyclosporine received marrow from the phenotypically HLA-identical father. The safety of the methotrexate/cyclosporine combination was first established in a pilot study including five patients (unpublished). Until Sept 13, 1984, Food and Drug Administration regulations prohibited the use of cyclosporine in children below the age of 12 years; these patients were excluded from either arm of the current study, and methotrexate was administered to all of them.

Patients were referred after detailed consultation with their physicians and admitted after outpatient and inpatient conferences that fully outlined the advantages and disadvantages of the transplantation procedure. Protocols and consent forms were approved by the Institutional Review Board at the Fred Hutchinson Cancer Research Center.

Before transplantation, all patients received cyclophosphamide, 50 mg/kg, intravenously (IV) on each of four successive days.[1,12,13] Thirty-six hours after the last dose of cyclophosphamide, donor marrow was infused IV. The day of marrow infusion was designated day 0. All multiply transfused patients 17 years and older were also given viable donor buffy coat cells as reported previously.[14,15]

Postgrafting immunosuppression was assigned by random permutations of a set of numbers known only to the protocol registrar. Assignment was stratified by patient age (≤25, >25 years), laminar airflow isolation room and decontamination, history of prior transfusion, and results of the relative response in mixed leukocyte culture. The relative response was obtained by comparing the response to sibling cells in a mixed leukocyte culture of patient cells to their response to pooled freshly drawn cells from two unrelated donors or cryopreserved cells from three unrelated donors; results were then expressed as a ratio, the relative response.[14,16] On the basis of data on

*In many cases, exact information on the transfusion history could not be obtained; the patients' records merely indicated that multiple transfusions had been administered.

212 healthy HLA-identical siblings, a positive relative response was defined as ≥2.6% and a negative one as <2.6%. The average relative response in this control group was 0.0%, with 2 SD = 2.6%. A positive relative response was interpreted to be an expression of transfusion-induced sensitization of the patient against the marrow donor. Only three patients given methotrexate/cyclosporine and one given methotrexate alone had a positive relative response of more than 2.6%[14,16]; in one patient given methotrexate, the relative response was not evaluable.

Patients randomized to receive methotrexate/cyclosporine were given methotrexate, 15 mg/m^2 IV on day 1 and 10 mg/m^2 on days 3, 6, and 11 postgrafting.[1] Reductions or omissions of methotrexate doses were common and were due to renal insufficiency, marrow toxicity, or liver function abnormalities associated with severe GVHD. Cyclosporine treatment was begun on the day before transplantation and was given IV at 1.5 mg/kg every 12 hours until recovery from chemotherapy-induced gastrointestinal toxicity.[7-9] At that time, patients were given cyclosporine orally at 6.25 mg/kg every 12 hours. The full dose of cyclosporine was given until day 50 unless nephrotoxicity developed; the dose was reduced by 50% if the serum creatinine level doubled above baseline values and was temporarily withheld if the creatinine value exceeded 2 mg/dL. After day 50 cyclosporine therapy was decreased by 5% per week and stopped 6 months after transplantation. Serum samples for the determination of cyclosporine levels were obtained three times weekly, 12 hours after the last cyclosporine dose. Samples were analyzed by radioimmunoassay.[17]

Patients randomized to receive methotrexate alone were given methotrexate, 15 mg/m^2, IV on day 1 and 10 mg/m^2 on days 3, 6, 11, and 18 and once weekly thereafter until day 102.[1] The methotrexate dose was reduced or occasionally held in case of renal impairment.

Sixteen patients given methotrexate/cyclosporine and 18 given methotrexate were treated in laminar airflow isolation rooms with skin and gut decontamination[18,19]; assignment to these rooms depended on availability. The remainder were treated in conventional reverse-isolation rooms.

Documentation of hematopoietic engraftment and assessment and grading and treatment of acute and chronic GVHD were done as previously described.[1,14,20] Primary therapy of established grades II to IV acute GVHD consisted of methylprednisolone, 2 mg/kg/d, either IV or orally in divided doses for a period of seven to 14 days when the patient's status was reevaluated.[21] Progressive GVHD was treated with antithymocyte globulin or, in the case of methotrexate-treated patients, with cyclosporine.[21-23] Chronic GVHD was treated with methylprednisolone, either alone or combined with azathioprine.[24] Routine marrow aspirates and cytogenetic studies were usually performed on days 14, 21, 28, 56, 84, and 365 postgrafting to assess the quality of engraftment.

Results of the study were analyzed as of Aug 31, 1985. The primary factor analyzed was the occurrence of grades II to IV acute GVHD. The summary analyses of the trial used Cox's relative risk regression model.[25] Kaplan-Meier estimates of the incidence of acute GVHD and of the survival curves for the two treatment arms were also calculated.[26]

RESULTS

Table 2 summarizes the postgrafting results.

Engraftment, transfusion support, early toxicities, and graft rejection. All 46 patients showed initial evidence of hematopoietic engraftment as determined by rising peripheral blood counts, marrow cellularity, and blood genetic marker studies. The speed of recovery of granulocyte counts and the time to discontinuation of platelet and RBC transfusion support were identical in the two groups, as was the incidence of oral mucositis. There was a significantly higher incidence of elevated bilirubin levels during the first 14 days after grafting in patients given methotrexate/cyclosporine compared with methotrexate alone. Renal function impairment was a frequent complication in patients given methotrexate/cyclosporine. Hypertension (diastolics ≥90 mm Hg on at least two separate daily measurements) was seen in nine patients given methotrexate/cyclosporine and six given methotrexate; four of the six patients receiving methotrexate prophylaxis, however, were being treated with additional cyclosporine for established GVHD. There was no significant difference between the two groups in the number of days spent in the hospital.

Cyclosporine trough levels for weeks 1, 2, 3, 4, 5, 6, and 7 (means ± 1 SD) were 99 ± 74, 148 ± 116, 134 ± 126, 187 ± 207, 105 ± 103, 120 ± 94, and 130 ± 82 ng/dL, respectively. Patients received approximately 75% of the calculated cyclosporine dose. Renal function impairment or marrow toxicity led to reductions in methotrexate doses in some patients. Specifically, 13 patients given the combination of drugs received 100% of the calculated methotrexate dose, three received between 80% and 90%, and six received less than 80%. Eight of the patients given methotrexate alone received 100% of the calculated drug dose, five received between 80% and 97%, and 11 received less than 80%. A major reason for reductions or omissions of methotrexate doses in this group of patients was severe liver function abnormalities in patients with grades III and IV acute GVHD.

One patient in each group rejected the marrow graft following initial engraftment. Both patients successfully received retransplants 194 and 203 days after the initial transplant, using marrow from the same donor and following a conditioning regimen consisting of cyclophosphamide, 50 mg/kg, on each of four successive days alternating every 12 hours with antithymocyte globulin, 30 mg/kg IV, for a total of three doses.[27] One patient is surviving more than 324 days after the first graft, and one died of complications associated with chronic GVHD on day 393.

Acute GVHD. Grades II to IV acute GVHD developed in 18% of the patients given methotrexate/cyclosporine compared with 53% of those given methotrexate alone (Fig 1). No patient receiving methotrexate/cyclosporine had grades III or IV acute GVHD compared with three and six patients, respectively, given methotrexate alone (Table 2). Table 3 gives relative risk estimates from a Cox regression model. The reduction in the incidence of acute GVHD in methotrexate/cyclosporine-treated patients was significant, even when other risk factors were considered. None of the other factors studied significantly altered the rate of acute GVHD, although a suggestively higher incidence was noted in patients older than 25 years.

Chronic GVHD. There was no statistically significant difference between the two patient groups with regard to the probability of chronic GVHD developing (Table 2). Mean

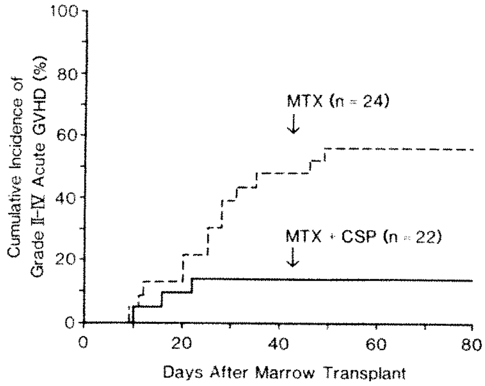

Fig 1. Probability of grades II to IV acute GVHD developing in 46 patients with severe aplastic anemia given marrow grafts from HLA-identical family members and GVHD prophylaxis with either methotrexate/cyclosporine (MTX + CSP) or methotrexate alone (MTX) (Kaplan-Meier product limit estimates[26]).

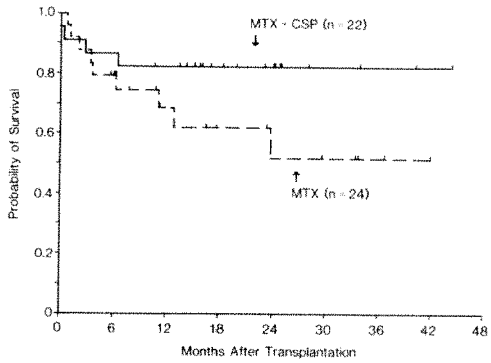

Fig 2. Probability of survival in 46 patients with severe aplastic anemia given marrow grafts from HLA-identical siblings and GVHD prophylaxis with either methotrexate/cyclosporine (MTX + CSP) or methotrexate alone (MTX) (Kaplan-Meier product limit estimates[26]). Tick marks represent surviving patients. Survival is as of Aug 31, 1985.

(median) Karnofsky performance scores among patients with chronic GVHD in the two groups are 85% (90%) and 83% (80%), respectively. All nine surviving patients with chronic GVHD in the methotrexate/cyclosporine-treated group and all six in the methotrexate-only group are presently receiving immunosuppressive treatment.[24]

Survival. The projected survival rate at 2 years is 82% for patients receiving methotrexate/cyclosporine compared with 60% for those receiving methotrexate alone (Fig 2). A Cox regression analysis (Table 3), also considering other prognostic factors, showed a suggestive survival advantage for the group receiving methotrexate/cyclosporine (P = .062). A significant beneficial influence on survival was the treatment of patients in laminar airflow room isolation. The influence of age on survival could not be assessed with this model since no patient below the age of 15 in either treatment group died.

Causes of death. Predominant causes of death were interstitial pneumonias and bacterial/fungal infections associated with GVHD (Table 2). This was most marked among patients receiving methotrexate only, with eight of the nine deaths attributable to these complications.

One patient given methotrexate died of interstitial pneumonia not associated with GVHD. He had had an unsuccessful course of immunosuppressive therapy with antithymocyte globulin before transplantation.

Among the patients given methotrexate/cyclosporine, veno-occlusive disease of the liver developed in one 43-year-old, and this patient died of hemorrhage on day 12. Another 40-year-old patient whose aplastic anemia was due to gold therapy of rheumatoid arthritis had an unsuccessful course of antithymocyte globulin therapy before transplantation. She was admitted with multiple bacterial/fungal brain and liver abscesses and died of these complications three days after transplantation.

Overall, nine of the 14 deaths in the two patient groups were related to complications from acute GVHD. Two additional patients died of problems associated with chronic GVHD.

Table 3. Cox Regression Analysis of Data on Acute GVHD and Survival

Factor	Relative Risk Estimates*	
	Grade II-IV Acute GVHD	Death
Preceding transfusions	2.76 (.131)	3.26 (.120)
Laminar airflow isolation	0.83 (.743)	0.12 (<.001)
Age 15-25 years	5.51 (.121)	
Age >25 years	6.76 (.077)	
Methotrexate/cyclosporine	0.18 (.012)	0.32 (.062)

*In parentheses are P values for testing the hypothesis that relative risk = 1.

DISCUSSION

Analogous with results in marrow-transplanted dogs,[28] three prospective clinical trials in patients with leukemia comparing methotrexate and cyclosporine treatment as single agents have shown either no or only marginal decreases in the incidence of acute GVHD in cyclosporine-treated patients without improving survival.[7-9] Subsequent experimental studies showed an impressive reduction of GVHD in dogs given a combination of methotrexate and cyclosporine. The survival rate of dogs given DLA-nonidentical unrelated marrow grafts was increased from 6% with either drug alone to 35% with the combination,[10] and that of recipients of DLA-haploidentical littermate marrow from 8% to 70%.[11] The current clinical trial was based on these experimental data. It showed methotrexate/cyclosporine therapy to be superior to methotrexate alone in preventing acute GVHD, thereby reducing the frequency of fatal infections and improving survival of patients given marrow grafts for severe aplastic anemia. Adjusting for age, the survival of patients given methotrexate alone was comparable to that reported previously.[4] FDA regulations prohibited the use of cyclosporine in patients below the age of 12 years for most of the current trial; historically, these young patients have a lower incidence of acute GVHD and better survival than older patients. The six patients excluded from this study because of young age were given methotrexate as GVHD prophylaxis, and all are surviving.

The long-term success of marrow grafting for the treatment of severe aplastic anemia depends on avoiding all of three mutually related complications: graft failure/graft rejection, GVHD, and severe infections. Any programs aimed at GVHD prevention must take the interrelationships between these three problems into account. It is conceivable that some graft-*v*-host reaction is required to eradicate residual host cells that survive the conditioning regimen. Such a possibility is in line with the clinical observation of a significant reduction in the incidence of graft rejection in patients given viable peripheral blood buffy coat cell infusions from the marrow donor.[14] Despite a significant decrease in the incidence and severity of GVHD in present patients given methotrexate/cyclosporine, graft failure was not a problem. In fact, only one patient in each study group rejected, although 35 of the 46 patients had had preceding transfusions. The reasons for the decrease in the incidence of rejection over previously reported figures are conjectural but may include lessened sensitization to non-HLA antigens through the use of buffy coat "free" red cell transfusions, single-donor platelet transfusions, and avoidance of family member transfusions before transplantation. Another indication for a lessened incidence of sensitization to blood products is the finding that only four of the current 35 transfused patients had a positive relative response in mixed leukocyte culture. This compares with the 20% to 30% reported by us previously.[16,29,30] These observations suggest that any program aimed at decreasing the incidence of rejection in transfused patients with aplastic anemia must take these changing conditions into account and emphasize the importance of randomized prospective studies. Other transplant teams have also observed reductions in the incidence of graft rejection, and this has been ascribed to the use of cyclosporine postgrafting, or total-lymphoid, total-body, or thoracoabdominal irradiation in the conditioning regimens.[3,5,6,31-34]

Patients with GVHD generally do not die of target organ failure, but rather of associated infectious problems. Effective GVHD prevention should lead to a reduction in the incidence of and mortality from infections, including interstitial pneumonias. This is evident in the current study where the number of deaths not associated with GVHD was comparable between the two treatment groups, whereas the number of deaths associated with GVHD and infections was fourfold greater among patients given methotrexate only. Reductions in the incidence of infections were seen by some but not all investigators in patients with leukemia in whom GVHD was avoided by the use of T cell–depleted marrow grafts.[35-37] A study from Minnesota showed a significant reduction in the incidence of acute GVHD with a combination of methotrexate, antithymocyte globulin, and prednisone compared with methotrexate alone, with no resultant benefit in survival, presumably because mortality from infections was not reduced.[38]

Although the incidence of acute GVHD and associated complications has been reduced and early survival improved in patients given methotrexate/cyclosporine, the incidence of chronic GVHD has been identical in the two treatment groups. Clearly, the combination of methotrexate and cyclosporine has not eliminated this problem. The lack of a difference between the two groups may in part be explained by the fact that many of those patients given methotrexate alone who would have been at highest risk for chronic GVHD developing[39] have died early of complications of acute GVHD, whereas comparable patients in the methotrexate/cyclosporine-treated group survived long enough to be at risk for chronic GVHD.

The use of laminar airflow room isolation, previously shown to reduce significantly the overall incidence of GVHD and increase survival,[40] had a less pronounced effect on the incidence of acute GVHD in the present study while continuing to show a significant beneficial effect on long-term survival. The effectiveness of methotrexate/cyclosporine in reducing the incidence and severity of acute GVHD may have in part obscured the beneficial influence of laminar airflow room isolation.

A major concern with regard to the use of any postgrafting immunosuppression is drug toxicity. The speed of recovery of blood counts and the incidence and severity of oral mucositis were similar in the two groups of patients; however, patients in the methotrexate/cyclosporine-treated group showed a higher incidence of transient liver function abnormalities, predominantly bilirubin elevations during the first 14 days. Presumably this was the result of an additive or synergistic toxic effect of methotrexate/cyclosporine combined with the toxicity of the conditioning regimen. Indeed, one patient in the methotrexate/cyclosporine group, aged 43 years, died of complications associated with severe veno-occlusive disease of the liver, presumably the result of drug toxicity. Other previously reported cyclosporine toxicities such as nephrotoxicity[41] and hypertension[42] were frequent findings in the present study. Nephrotoxicity is a particular problem during the early postgrafting period, potentiated by the use of nephrotoxic antibiotics including amphotericin B.[43] The early renal function abnormalities required reduction or omission of methotrexate and cyclosporine doses in some patients. The impact of drug dose reductions or omissions on subsequent development of acute GVHD is difficult to evaluate. The fact that more patients given methotrexate required dialysis was probably related to the fact that these patients had severe acute GVHD for which they were given additional treatment with cyclosporine.

We conclude that the combination of methotrexate and cyclosporine resulted in a significant decrease in the incidence and severity of acute GVHD in patients who received transplants for severe aplastic anemia, with a resultant improvement in survival. However, the latter conclusion is only tentative since follow-up of these patients is still short, with the longest survivor at 4 years.

ACKNOWLEDGMENT

We are indebted to the inpatient and outpatient physicians, nurses, ward clerks, secretaries, technologists, and data processors of the Fred Hutchinson Cancer Research Center and Swedish Hospital Medical Center for their cooperation in this study. We thank Dr G. Yee for determining cyclosporine levels. We would also like to thank Dr D. Winter, Sandoz Inc, East Hanover, NJ, for his continued support and for supplying cyclosporine.

Enhancement of the Proliferation of Human Marrow Erythroid (BFU-E) Progenitor Cells by Prostaglandin E Requires the Participation of OKT8-Positive T Lymphocytes and Is Associated With the Density Expression of Major Histocompatibility Complex Class II Antigens on BFU-E

By Li Lu, Louis M. Pelus, Hal E. Broxmeyer, Malcolm A.S. Moore, Maria Wachter, Donald Walker, and Erich Platzer

The relationship between major histocompatibility complex class II antigens (MHC class II, eg, HLA-DR, Ia), T lymphocytes, and the enhancement of erythroid colony formation from BFU-E by prostaglandin E was analyzed using normal bone marrow cells. In primary methylcellulose culture, the addition of prostaglandin E_1 (PGE_1) to unseparated buffy coat, low-density, or nonadherent low-density (NAL) marrow cells resulted in an enhancement of the total number of erythroid (BFU-E) colonies observed. Treatment of bone marrow cells with a monoclonal antihuman MHC class II antibody plus complement (C′) resulted in a reduction of the total number of colonies by approximately 50% and abrogation of the enhancing effect of PGE_1. Analysis of accessory cell requirements by depletion of both adherent cells and sheep erythrocyte rosetting lymphocytes (E^+ cells) and reconstitution using C′ or anti-MHC class II antibody plus C′-treated T cell-depleted NAL ($NALT^-$) marrow cells and E^+ cell populations treated with C′ or anti-MHC class II antibody plus C′ demonstrated a requirement for MHC class II antigen$^-$ T cells, but not adherent cells, and a requirement for MHC class II antigen+ BFU-E in order to observe the enhancing effect of PGE_1 on erythroid colony formation. Positive selection of BFU-E in $NALT^-$ bone marrow expressing differing density distributions of MHC class II antigens was accomplished with monoclonal anti-MHC class II antibodies and sorting with a fluorescence-activated cell sorter (FACS). Addition of E^+ cells to the different populations of MHC class II antigen$^+$ $NALT^-$ cells demonstrated that the PGE-enhancing effects on erythroid colony formation were directly related to increasing density distributions of MHC class II antigens on BFU-E. Colony formation by BFU-E expressing a low density distribution of MHC class II antigens or having no detectable MHC class II antigens, as determined by FACS analysis, was not enhanced by PGE_1 in the presence of MHC class II antigen-positive or -negative T cells.

A RELATIONSHIP between expression of major histocompatibility complex (MHC) class II antigens (eg, HLA-DR, Ia) on human bone marrow multipotential (CFU-GEMM), erythroid (BFU-E), and granulocyte-macrophage (CFU-GM) progenitor cells during DNA synthesis and the regulatory effects of prostaglandin E (PGE) and acidic isoferritins on the proliferation of these cells in vitro has been reported.[1-5] We[6,7] as well as others[8] have shown that PGE has the capacity to augment the number of human marrow BFU-E colonies that can be detected in vitro. In addition, we have implicated MHC class II antigens in the erythroid-enhancing effect of PGE on BFU-E.[6]

Considerable evidence has accumulated indicating that either T lymphocytes[9-12] or monocytes-macrophages,[8,13-17] both cell populations,[18-21] or other cells[22] play roles in the regulation of BFU-E proliferation. In this report, we have investigated the role of accessory cells and MHC class II antigens on the enhancement of bone marrow BFU-E proliferation by PGE_1. Evidence is presented that indicates that PGE_1 specifically enhances colony formation by BFU-E expressing a high density distribution of MHC class II antigens and that this effect requires the participation of a population of $OKT8^+$ lymphocytes that do not have to express MHC class II antigens.

MATERIALS AND METHODS

Cells and cell separation procedures. Bone marrow cells were obtained by aspiration from the posterior iliac crest of healthy volunteers who had given informed consent. Unseparated nucleated buffy coat cells were obtained by centrifugation of whole marrow aspirates at 1,500 rpm for 10 minutes and aspiration of the white cells that overlay the red cell layer. Low-density cells (LD, <1.077 g/mL) were obtained after separation on Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) at 1,500 rpm for 30 minutes, washed three times, and resuspended in Iscove's modified Dulbecco's medium (IMDM, GIBCO, Grand Island, NY) containing 10% fetal calf serum (FCS, Hyclone, Sterile Systems, Inc, Logan, Utah). Cells were further separated into nonadherent and adherent cells after incubation on plastic tissue culture dishes (Falcon 3003, Falcon Plastics, Division of Becton Dickinson, Rutherford, NJ) for 90 minutes at 37 °C in 5% CO_2. Nonadherent cells were collected by gently swirling the dishes and slowly removing the suspension cells. Nonadherent cells prepared in this manner routinely contained $<2\%$ naphthyl-acetate-esterase-positive cells. Adherent cells were obtained using a rubber policeman after washing the dishes five times. The adherent cell fraction contained 90% to 98% monocytes/macrophages as determined by naphthyl-acetate-esterase staining.

Nonadherent low-density cells (NAL) were further separated into E rosette-positive (E^+) and -negative (E^-) populations according to a method modified from Weiner et al.[23] Briefly, sheep erythrocytes

(SRBC) were washed three times in Ca^{++}-free and Mg^{++}-free phosphate-buffered saline (PBS), resuspended at 5% (vol/vol) in medium, and treated with neuraminidase (Calbiochem-Behring Corp, La Jolla, Calif) for 30 minutes at 37 °C. After two washes, 1 mL of 5% neuraminidase-treated SRBC was mixed with 10 mL of NAL marrow cells (4×10^6 cells/mL), incubated for five to ten minutes at 37 °C, centrifuged at 1,000 rpm for five minutes, and allowed to stand for 90 minutes at 4 °C. The pellet was then resuspended gently, placed on Ficoll-Hypaque, and centrifuged at 2,000 rpm for 20 minutes. Interface cells were washed three times and constituted the T cell–depleted NAL (NALT$^-$) fraction. Rosette-forming cells recovered in the pellet were treated with Tris–ammonium chloride to lyse the SRBC, washed three times, and constituted the E+ fraction. The E+ fraction contained approximately 95% T cells as determined using the OKT11a (anti-SRBC) pan–T cell antibody. The NALT$^-$ marrow cell fraction usually contained about 5% OKT11a$^+$ cells and were treated with OKT11a and complement (C′) to remove remaining T lymphocytes.

Analysis of T lymphocyte subsets. The purity of the T cell populations was analyzed by indirect immunofluorescence using a FACS IV (Becton Dickinson, Sunnyvale, Calif). One million cells were incubated with 1:50 dilutions of monoclonal anti–T lymphocyte antibodies for 40 minutes at 4 °C, washed three times, and then incubated with a 1:40 dilution of affinity-purified goat antimouse IgG F(ab′)$_2$ fluorescein isothiocyanate (FITC) (Cappel Laboratories, Cochranville, Pa) for 40 minutes at 4 °C. After washing three times, cells were brought up to 1 mL with PBS for fluorescein-activated cell sorter (FACS) analysis. Cells were maintained at 4 °C until analyzed.

Positive selection of T lymphocyte subsets. E$^+$ cells were sorted into monoclonal antibody–positive and –negative populations using a FACS IV or FACS 440. Ten million cells were treated in 0.5 mL of medium containing OKT4 or OKT8 antibodies at a final dilution of 1:200 for 40 minutes at 4 °C. Following incubation, the cells were washed three times and treated with FITC-labeled goat antimouse IgG (heavy + light, F(ab′)$_2$) for 40 minutes at 4 °C. The cells were subsequently washed three times and resuspended in PBS with 1% FCS for sterile sorting. The gating criteria on the FACS were set for high (positive) and low (negative) fluorescence intensity windows separated by an intermediate zone of 40 channels containing approximately 40% of the sorted cells, which were discarded.[24] After sorting, the recovered high- and low-fluorescent intensity cell populations were washed twice and resuspended in media containing 10% FCS. The viability of sorted cells was greater than 95% using trypan blue. The purity of sorted cells was analyzed immediately by indirect immunofluorescence using a FACS. All monoclonal antibodies were dialyzed to remove contaminating sodium azide prior to being used for cell sorting.

Positive selection of NALT$^-$ marrow cells expressing different density distributions of MHC class II antigens. NALT$^-$ cells were sorted with a FACS using monoclonal anti-MHC class II antibody (1:200 dilution) into populations containing high (Ia^{+++}), medium (Ia^{++}), low (Ia$^+$), or nondetectable (Ia$^-$) density distributions of MHC class II antigens as previously described for sorting of T cell subsets. Since only two windows can be collected at a time and we wished to achieve the best separation of cells based on antigen density, cells were sorted at one time for Ia^{+++} and Ia$^+$ or for Ia^{++} and "Ia$^-$" densities. The other fractions were not used. After sorting, the cells were washed and plated. Analysis of these populations was done after sorting.

Antibody and C′-dependent cytotoxicity test. All antibodies were used at specific final dilutions, predetermined for optimal activity, on cells suspended at a density of one million cells per 0.1 mL. Rabbit C′ (Low Tox-H) was purchased from Accurate Chemical Co, Westbury, NY, and used at a 1:8 dilution. Antibody plus C′ cytotoxicity reactions were carried out as described previously.[1-4] Cells were washed twice and brought back to their original starting volume prior to plating.

Assay. Bone marrow cells were plated at the concentration listed in the table legends, or what was left after antibody and C′ treatment, in 35-mm Lux standard tissue culture dishes containing a 1-mL mixture of IMDM, 1% methylcellulose, 30% FCS, 5% medium conditioned by leukocytes (LCM) from patients with hemochromatosis in the presence of 1% phytohemagglutin (PHA-LCM) and 5×10^{-5}mol/L 2-mercaptoethanol. Hemin was added in the dish at a concentration of 0.1 mmol/L when LD, NAL, or NALT$^-$ cells were used to increase the cloning efficiency of BFU-E and CFU-GEMM.[7,25] Cells were plated with or without PGE$_1$. One unit of a Step III preparation of sheep plasma erythropoietin (Connaught Laboratories, Ltd, Willowdale, Ontario, Canada or Hyclone, Sterile Systems, Logan, Utah) was added to the dish on day 0. Indomethacin was used at a final concentration of 10^{-6}mol/L to prevent endogenous prostaglandin production.[3] Dishes were incubated at 37 °C in a humidified atmosphere flushed with 5% CO$_2$ in air. Colonies were scored after 14 days of incubation.

Reagents. The monoclonal antihuman MHC class II antibody NEI-011 was purchased from New England Nuclear, Boston. Monoclonal antihuman T cell antibodies OKT3, OKT4, and OKT8 were purchased from Ortho Pharmaceutical Corp, Raritan, NJ. PGE$_1$ was used at a final concentration of 10^{-7}mol/L. Indomethacin was used at a final concentration of 10^{-6}mol/L. Both PGE$_1$ and indomethacin were purchased from Sigma Chemical Co, St Louis. Bovine hemin was purchased from Eastman Kodak Co, Rochester, NY, and was prepared in 0.5 mol/L NaOH and then neutralized with 1 N HCl as described.[25]

Statistical analysis. Levels of significance for comparisons between samples were determined using Student's *t* distribution. The results are expressed as the mean ± 1 SEM of four or five plates per point for each experiment.

RESULTS

Influence of accessory cell populations on the enhancement of erythroid colony formation from BFU-E by PGE$_1$. The addition of 10^{-7}mol/L PGE$_1$ to cultures containing BFU-E in unseparated (buffy coat), LD, or NAL bone marrow cells resulted in a significant enhancement of erythroid colony formation from BFU-E (67 ± 17, 64 ± 11, and 48 ± 9%, respectively, average for three experiments) in comparison with control cultures (Table 1). In all cases, treatment of these marrow cell populations with a monoclonal anti-MHC (α-MHC) class II antibody plus C′ decreased the total number of erythroid colonies detected by 47% to 58% and abrogated the enhancing effect of PGE$_1$ on colony formation. Removal of T lymphocytes from NAL marrow cells by rosetting with sheep erythrocytes resulted in the inability to detect PGE$_1$ enhancement of erythroid colony formation from BFU-E, suggesting that T lymphocytes may be needed to observe PGE$_1$ enhancement of BFU-E proliferation. Treatment of NALT$^-$ bone marrow with α-MHC class II antibody plus C′ removed approximately 48% of BFU-E in a similar fashion to its effect on buffy coat, LD, or NAL marrow cells.

Influence of T lymphocytes and monocytes-macrophages on the enhancement of erythroid colony formation from BFU-E by PGE$_1$. The effects of T lymphocytes and monocytes-macrophages on the enhancement of BFU-E colony formation by PGE$_1$ were evaluated using cell depletion and

reconstitution experiments (Table 2). LD bone marrow cells were depleted of E^+ and plastic adherent cells and reconstituted with various ratios of either or both cell populations. The addition of E^+ marrow cells to NALT$^-$ marrow restored the enhancing effect of PGE_1 on erythroid colony formation (range, 19% to 67%, four experiments) using E^+:NALT$^-$ ratios of 0.5:10 (5% E^+) to 4:10 (40% E^+). Maximal activity was observed at an E^+:NALT$^-$ ratio of 1:10 (10% E^+). Reconstitution of NALT$^-$ marrow cells with plastic adherent cells at ratios of 5% to 40% failed to restore the enhancing effect of PGE_1 on erythroid colonies and resulted in significant dose-dependent (30% to 84%) inhibition of the number of detectable erythroid colonies. The addition of both E^+ and adherent cells at ratios of 5% and 10% were as effective as E^+

cells alone in restoring the erythroid-enhancing effect of PGE$_1$. However, at ratios of 20% and 40%, they were less effective than E$^+$ cells alone, perhaps because of the inhibitory influences of the adherent cells. Neither E$^+$ nor adherent cells alone were capable of erythroid colony formation in the presence of erythropoietin and hemin (data not shown). The purity of E$^+$ cells was about 95% as determined by immunofluorescence using the monoclonal anti-SRBC receptor antibody OKT11a. The purity of adherent cells was >95% using napthyl-acetate-esterase staining.

The effect of PGE$_1$ on erythroid colony formation by MHC class II antigen–positive BUF-E. To define an accessory T lymphocyte requirement for PGE$_1$-mediated enhancement of erythroid colony formation and to identify the MHC class II antigen–positive participating cell population(s), NAL marrow cells were depleted of T lymphocytes, treated with or without α-MHC class II plus C′, and reconstituted with untreated E$^+$ cells or E$^+$ cells treated with MHC class II plus C′ prior to their addition to NALT$^-$ marrow cells (Table 3). As observed previously, removal of T lymphocytes from NAL marrow by rosetting with sheep erythrocytes resulted in the inability to observe any enhancing effect of PGE$_1$ on erythroid colony formation. Furthermore, treatment of NALT$^-$ marrow cells with MHC class II plus C′ resulted in approximately a 48% reduction in the number of detectable BFU-E. Reconstitution of NALT$^-$ bone marrow cells with E$^+$ marrow cells at a ratio of 1:10 (E$^+$:NALT$^-$) resulted in the restoration of the enhancing effect of PGE$_1$ on erythroid colony formation from BFU-E (63% ± 7%, five experiments). Treatment of E$^+$ cells with MHC class II antibody plus C′, which removed MHC class II$^+$ E$^+$ cells, prior to their addition to NALT$^-$ marrow did not affect the ability of these cells to restore the enhancing effect of PGE$_1$ on erythroid colony formation (59% ± 10%, five experiments). In contrast, treatment of NALT$^-$ marrow cells with MHC class II antibody plus C′ reduced the number of erythroid colonies detected and blocked the enhancing effect of PGE$_1$ on erythroid colony formation following reconstitution with either untreated E$^+$ cells or MHC class II antibody plus C′-treated E$^+$ cells.

The influence of the density distribution of MHC class II antigens on NALT$^-$ cells on the enhancement of erythroid colony formation by PGE$_1$ in the presence of added T lymphocytes. To evaluate further the relationship between expression of MHC class II antigens on BFU-E and the enhancing effect of PGE$_1$ on erythroid colony formation, NALT$^-$ cells were separated by FACS into fractions with Ia^{+++}, Ia^{++}, Ia$^+$, and "Ia$^-$" density distributions of MHC class II antigens. A representative presorting pattern of antigen-positive cells is shown in Fig 1, and a representative postsorting pattern of antigen-positive cells with differing fluorescent intensities is shown in Fig 2. In this experiment,

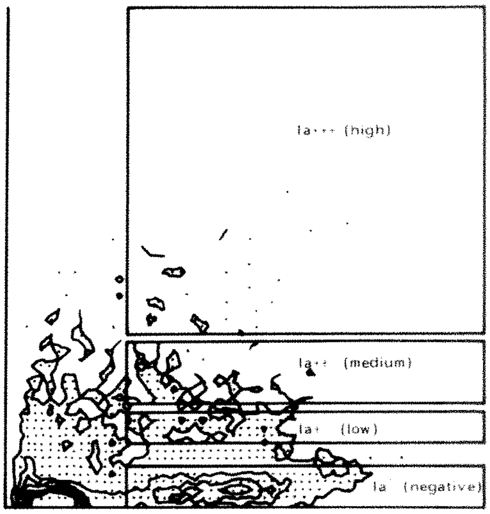

Fig 1. Representative analysis on the FACS 440 of the density distribution of MHC class II (Ia) antigens on NALT$^-$-bone marrow cells using a monoclonal antihuman MHC class II antibody (NE1-011) before sorting (x axis, forward light scatter; y axis, fluorescence intensity). Gating windows were set as follows: channels 0 to 20 contained 32% of the cells and were designated "Ia$^-$", channels 32 to 48 contained 4.8% of the cells and were designated Ia$^+$, channels 52 to 84 contained 5% of the cells and were designated Ia^{++}, and channels 88 to 255 contained 6.6% of the cells and were designated Ia^{+++}.

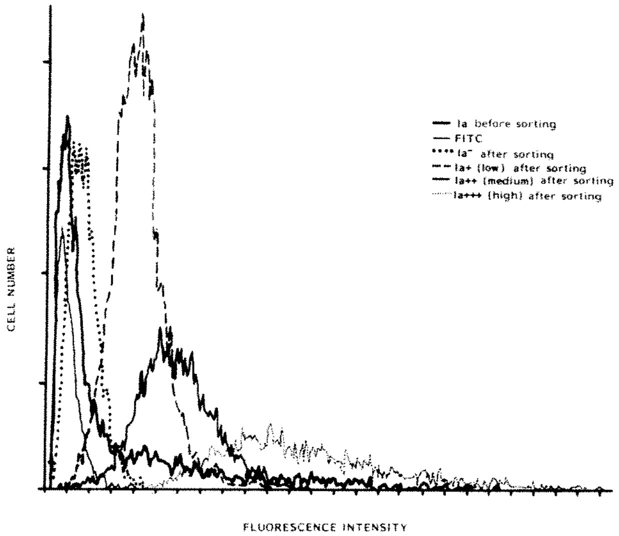

Fig 2. Profile of the density distribution of MHC class II antigen–positive cells after cell sorting on the FACS 440. The "Ia$^-$", Ia$^+$, Ia^{++} and Ia^{+++} cell fractions contained respectively at least 4%, 80%, 90%, and 92% of the cells staining for MHC class II antigens.

the "Ia$^-$", Ia$^+$, Ia^{++}, and Ia^{+++} cell fractions contained respectively at least 4%, 80%, 90%, and 92% of the cells staining for MHC class II antigens. In some experiments the "Ia$^-$" fraction contained <2% MHC class II antigen–positive cells, and the MHC class II antigen–positive fractions were composed of >95% MHC class II antigen–positive cells. The actual colony numbers for one representative experiment and the average percent change from control for three experiments using the sorted populations of NALT$^-$ cells differing in density distributions of MHC class II antigens are shown in Table 4. Because of the overlap of the Ia^{++} population with the Ia$^+$ and Ia^{+++} cells, only the "Ia$^-$", Ia$^+$, and Ia^{+++} cells were evaluated. In the presence of E$^+$ cells, PGE$_1$ enhanced erythroid colony formation by Ia$^+$ NALT$^-$ and Ia^{+++} NALT$^-$ cells, but did not enhance colony formation by the "Ia$^-$" NALT$^-$ cells. The enhancement in colony formation was greater for the cells expressing a higher density distribution of MHC class II antigens (Ia^{+++}) than for the cells expressing a lower density distribution of these antigens (Ia$^+$) and was respectively +154% ± 43% and +43% ± 10% for the two responding cell populations. The greater enhancement in erythroid colony formation using the Ia^{+++} population of cells was not due to a lower control number of Ia^{+++} *v* Ia$^+$ cells since in some of the experiments the control number of Ia^{+++} cells was higher than the control number of Ia$^+$ cells. Results were similar whether the MHC class II antigen$^+$ NALT$^-$ cells were cultured with E$^+$ cells pretreated with control medium, C′, or MHC class II plus C′ (data not shown).

Influence of T lymphocytes and their subsets on erythroid colony enhancement by PGE$_1$. The effects of treatment of bone marrow cells with monoclonal anti–T cell antibodies in the presence or absence of C′ on the enhancement of colony formation from BFU-E by PGE$_1$ were analyzed (Table 5). Treatment of unseparated bone marrow cells with either the pan-T cell antibody (OKT3 (1:50 dilution) or the T subset-specific OKT8 (1:50 dilution) antibody in the presence of C′ resulted in the inability to detect PGE$_1$-mediated enhancement of erythroid colony formation from BFU-E (2% ± 6%, 6% ± 2% enhancement, respectively, three experiments). In contrast, treatment of marrow cells with the T subset-specific OKT4 (1:50 dilution) antibody plus C′ was without effect on PGE$_1$-mediated erythroid enhancement (31% ± 4% enhancement, three experiments). In the absence of C′, pulse exposure of marrow cells for 30 minutes with OKT8 antibody was able to block the enhancing effect of PGE$_1$ on erythroid colony formation (18% ± 4% enhancement, three experiments), whereas OKT3 and OKT4 were without effect (59% ± 24%, 64% ± 12% enhancement, three experiments).

In the presence of antibody plus C′ the appropriate cell populations were killed, and in the presence of antibody without C′ there was no effect on cell viability.

The effect of positively selected OKT8$^+$ T lymphocytes on the enhancing effect of PGE_1 on erythroid colony formation. The requirement for OKT8$^+$ T lymphocytes to observe PGE_1 enhancement of erythroid colony formation was further analyzed by positive selection of T lymphocyte subsets by sorting using the monoclonal OKT4 and OKT8 antibodies (1:200 dilution) and the FACS IV. The E$^+$ fraction of bone marrow cells was labeled with either OKT4 or OKT8 and sorted into positive and negative populations. Prior to sorting, the E$^+$ cell fraction contained >90% OKT11a$^+$ (SRBC$^+$) T cells with approximately >30% OKT4$^+$ and >60% OKT8$^+$ cells. After sorting, the OKT4$^+$ and OKT8$^+$ cell fractions contained ≥98% and ≥97% positive cells, respectively. The OKT4$^-$ and OKT8$^-$ cell fractions contained <2% cells positive for OKT4 and OKT8.

Sorted cells were added back to NALT$^-$ narrow cells (from the same donor) at ratios of 1%, 5%, 10%, 20%, and 40% (Table 6). The addition of OKT8$^+$ or OKT4$^-$ cell populations restored the ability of NALT$^-$ marrow cells to respond to the erythroid colony enhancing effect of PGE_1. Optimal activity was observed at T4$^-$ or T8$^+$:NALT$^-$ ratios of 1:10 (10%). The addition of OKT4$^+$ or OKT8$^-$ cell fractions to NALT$^-$ marrow failed to result in restoration of the enhancement of erythroid colony formation from BFU-E by PGE_1. Each of the sorted cell populations was incapable of colony formation by themselves (data not shown).

Table 6. Influence of Purified Positively Selected Marrow T Lymphocyte Subpopulations on the Enhancement of Erythroid Colony Formation From BFU-E by PGE_1

Cells*	Percent Change From Media Control in the Presence of 10^{-7} mol/L PGE_1†	Number of Experiments
NALT$^-$	+1 ± 2	3

DISCUSSION

Most or all erythroid progenitor cells express MHC class II (eg, HLA-DR, Ia) antigens on their cell surface,[26–28] although there is heterogeneity of density expression of these antigens on erythroid progenitors.[28] A role for MHC class II antigens on BFU-E and the regulation of erythropoiesis in vitro[1,6,11,12] and a role for MHC class II antigens in the enhancement of erythroid colony formation from BFU-E by PGE have been suggested.[6] This latter information has now been extended to demonstrate the participation of marrow T lymphocytes having the OKT8 subset phenotype in the selective enhancing effect of PGE_1 on colony formation by BFU-E and to show that this enhancing activity is directly associated with an increasing density distribution of MHC class II antigens on BFU-E.

The removal of bone marrow T lymphocytes using (1) selection for E^+ ($SRBC^+$) cells, (2) negative selection using purified anti-T cell monoclonal antibodies in a C′-mediated cytotoxicity assay, and (3) positive selection of subsets of marrow T lymphocytes using monoclonal antibodies and FACS sorting combined with recombination experiments indicate a requirement for OKT8 antigen-positive bone marrow T lymphocytes to observe the enhancing effect of PGE_1 on erythroid colony formation. In this regard, it is of interest that $OKT8^+$ T lymphocytes are the predominant T lymphocyte population found in human bone marrow.[29] Of interest to the $OKT8^+$ cell-mediated effect is that OKT8 antibody in the absence of C′ blocks the PGE enhancement of erythroid colony formation. This suggests that the antigenic determinant recognized by OKT8 antibody may be involved in these interactions, but this remains to be determined.

Cellular actions and interactions in the control of in vitro erythropoiesis have been an area of intensive investigation. Studies have shown that the proliferation of BFU-E can be modulated, either enhanced or inhibited, by normal peripheral blood T lymphocytes and their subpopulations, monocytes and macrophages, other cells, or combinations of these cells.[9-22] In this report, we do not directly address the question of cellular involvement in the control of BFU-E proliferation, but rather we have focused on accessory cell involvement in the erythroid-enhancing effect noted with PGE_1. Our data using marrow BFU-E are consistent with an enhancing effect of bone marrow T lymphocytes mediating the PGE_1 effect and an inhibitory effect of marrow adherent cells on the proliferation of BFU-E. The inhibitory effect of marrow adherent cells on BFU-E most likely reflects their production of acidic isoferritins, which are inhibitory of BFU-E proliferation.[1] This inhibitory effect could be abrogated by use of an antiacidic isoferritin antisera (L. Lu, unpublished observation). Our populations of $NALT^-$ marrow cells were not completely devoid of T cells and/or adherent cells, which is the case with almost all the other studies describing effects of accessory cells on proliferation of BFU-E. Therefore, sufficient residual cells may have remained or may have been generated during the culture period to mediate accessory cell function, at least with respect to their requirement for BFU-E proliferation. It should also be noted that we used bone marrow BFU-E and T cells, which is in contrast to the predominant use of peripheral blood BFU-E and accessory cells by other investigators. Also, our culture conditions permit the simultaneous detection of BFU-E and multipotential CFU-GEMM colonies, which differs from the conditions used in the experiments of other investigators. Our cultures contained a source of burst-promoting activity present in PHA-LCM. We have shown elsewhere that the effects of PHA-LCM and PGE are additive on enhancing erythroid colony formation.[7] Of direct relevance to a role for monocytes in the regulation of erythroid colony formation is that monocytes produce PGE_1.[30] Thus, monocytes have the potential (1) to enhance colony formation via the release of PGE_1, which could act via the $OKT8^+$ lymphocyte pathway, and (2) to suppress colony formation via the release of inhibitory molecules such as acidic isoferritins.[1] We had purposely added indomethacin to our cultures to suppress the production of prostaglandins so that we could assess the role of exogenously added PGE_1. Our preliminary results indicate that PGE_1 stimulates the release into conditioned medium of an erythroid-enhancing activity from sorted $OKT8^+$ cells (purity >98%), which when added to $NALT^-$ marrow cells restores the erythroid-enhancing effect of PGE_1.[31] Although these results suggest the T cell derivation of an erythroid-enhancing activity, they cannot exclude an effect of this factor mediated via an additional marrow accessory cell. Further studies using more purified marrow BFU-E populations are required to elucidate this point.

In a previous report, we had presented evidence that suggested a link between MHC class II antigen expression and the enhancement of erythroid colony formation by PGE.[6] However, these studies did not discriminate between an effect upon MHC class II $antigen^+$ BFU-E or an effect mediated via MHC class II antigen-positive accessory cells. In this study, treatment of T-depleted marrow cells and positively selected T lymphocytes with a monoclonal MHC class II antibody plus C′ prior to their being recombined suggests that PGE_1 with the participation of MHC class II antigen-negative T cells selectively enhances the proliferation of MHC class II antigen-positive BFU-E. The data shown in Tables 1 and 3 using monoclonal anti-MHC class II antibody plus C′ to remove 50% of BFU-E and to remove completely the cell populations responding to the enhancing effects of PGE_1 in combination with the data shown in Table 4 evaluating the effects of PGE_1 on the MHC class II antigen-positive cells sorted by FACS are consistent with increasing responsiveness of BFU-E to this enhancing effect being associated with an increasing density distribution of MHC class II antigens on BFU-E. That we were killing only 50% of BFU-E by monoclonal anti-MHC class II plus C′ most likely reflects removal mainly of cells with a higher density distribution of MHC class II antigens. This has been noted for CFU-GM where S-phase cells express a higher density distribution of MHC class II antigens.[2,32] Even by FACS analysis using the Nel-011 antibody, a portion of BFU-E did not contain detectable levels of MHC class II antigens. This may reflect a very low density of antigens on these cells.

It is difficult to extrapolate from findings in vitro to relevance in vivo, especially when so many complex cell interactions are noted in vitro where several different populations of cells alone or in collaboration can produce erythroid burst-promoting activities. The physiologic significance of these molecule-cell interactions remains to be determined.

3A1 (CD7) Expression Precedes T_β Gene Rearrangements In Precursor T (Lymphoblastic) Neoplasms

By Stefania Pittaluga, Mark Raffeld, Edward H. Lipford, and Jeffrey Cossman

The phenotypes of early stages of T cell maturation are reflected by precursor T (lymphoblastic) neoplasms. In the present study, a series of such neoplasms was analyzed to reveal the developmental association of the expression of stage-related cell surface markers and T cell receptor gene rearrangement. Rearrangements of the T cell receptor β-chain (T_β) gene were found in most, but not all, cases (88%) of T cell lymphoblastic neoplasms. T_β gene rearrangement preceded surface expression of the T cell receptor-linked molecular complex T3. Of all monoclonal anti-T cell antibodies tested, only antibody 3A1 was capable of reacting with neoplastic cells from all cases irrespective of the occurrence of T cell receptor gene rearrangements. In contrast, markers T1 and T11, normally expressed by mature T cells, were absent from the neoplastic cells in many cases (73% and 60% positive cases, respectively). Thus, antibody 3A1 is a valuable probe for the identification of T lymphoblastic neoplasms since its target antigen is consistently expressed and does not require prior T_β gene rearrangement. Furthermore, expression of 3A1 prior to T_β gene rearrangement suggests that it may be a cell surface protein that participates in the triggering of T cell receptor gene rearrangement and expression. It is concluded that precursor T cell neoplasms display an early T cell development hierarchy that, in sequence, consists of 3A1 expression, T_β gene rearrangements, and surface T3 expression.

THE DIFFERENTIATION of T cell precursors into mature effector cells occurs in the thymus and is associated with the acquisition of functional cell surface membrane molecules. As a consequence, the developmental pathway of early T cells can be characterized by the detection of these sequentially expressed surface molecules using a series of monoclonal antibodies (e.g., T3, T6, T11, etc).[1] A critical feature acquired by T cells is their capacity to recognize unique antigens. This is achieved during thymocyte differentiation whereby genes encoding the specificity of the T cell antigen-specific receptor undergo rearrangement in a manner reminiscent of immunoglobulin genes in pre-B cells.[2-5] As thymic T cells mature, the translational products of the rearranged genes become assembled as an immunoglobulinlike heterodimer composed of one α and one β chain.[6] Expression of surface membrane T cell antigen receptors is thought to be dependent on the obligatory coexpression of and noncovalent linkage with the invariant protein T3.[7]

Neoplasms of immature T cells, lymphoblastic leukemias, and lymphomas express thymocyte phenotypes, have a striking propensity for intrathymic growth, and appear to be neoplastic counterparts of thymocytes arrested in distinct developmental stages.[1,8-12] Recognition of the precursor T cell phenotype of T lymphoblastic neoplasms has provided the basis for immunophenotypic analysis as a clinically critical diagnostic and classification tool.[11-14] Because of their immature T cell phenotype, we reasoned that lymphoblastic neoplasms might reflect phenotypes associated with the T cell receptor gene rearrangement process. Moreover, T cell neoplasms are clonal expansions, and consequently, their uniformly rearranged T cell receptor genes are readily amenable to restriction enzyme analysis.[15-20]

In the present study we have examined T cell receptor β-chain (T_β) gene rearrangements in a series of human precursor (lymphoblastic) T cell neoplasms to evaluate the developmental relationship between gene rearrangement and cell surface protein expression. Evidence presented demonstrates the diagnostic application of molecular genetics to precursor T cell neoplasms, since the majority have undergone T_β rearrangement and are clonal, T lineage cells. Moreover, the series of precursor T cell neoplasms displays an early T cell developmental hierarchy that in sequence, consists of 3A1 expression, T_β gene rearrangement, and T3 expression. Gene rearrangements in precursor T cell neoplasms underscore the valuable contribution of molecular genetics to diagnostic pathology and provide insight into the developmental events surrounding T_β gene rearrangement.

MATERIALS AND METHODS

Precursor T cell neoplasms. All lymphoproliferative processes were classified by conventional microscopy as either acute lymphoblastic leukemia or malignant lymphoma, lymphoblastic. Viable cell suspensions stored in the vapor phase over liquid nitrogen were used for cell surface marker studies and DNA extraction as described.[17] In each case >80% of cells were morphologically neoplastic, reacted with at least one anti-T, but not B1 and B4, monoclonal antibody, and contained terminal deoxynucleotidyl transferase as shown by antibody staining of fixed cytocentrifuge preparations, as previously outlined.[12,21]

Cell surface phenotyping. Washed, viable cells were treated with monoclonal antibodies and analyzed by indirect immunofluorescence in a fluorescence-activated cell sorter (FACS II, Becton Dickinson, Sunnyvale, Calif) as described.[12,21] Cells were scored positive when >20% of the lymphoblasts reacted with antibody. Monoclonal antibodies and their antigen targets (in parentheses) were B1, B4, 3A1 (CD7), Leu-1 (T1, CD5), Leu-2 (T8, CD8), Leu-3 (T4, CD4), Leu-4 (T3, CD3), OKT6 (T6, CD1), OKT11 (T11, CD2), Lyt 3/9.6 (T11, CD2), J5 (common acute lymphoblastic leukemia antigen, CALLA, CD10), and HLA-DR. Antibodies were obtained from the following sources: B1, B4, and J5 (Coulter Immunology, Hialeah, Fla); OKT6 and OKT11 (Ortho Pharmaceutical Corp, Raritan, NJ); Leu series and HLA-DR (Becton Dickinson); Lyt 3/9.6 (New England Nuclear, Boston) and 3A1 (American Type Culture Collection, Rockville, Md).

Southern blot hybridization. High–molecular weight genomic DNA was extracted from lymphoid cells and digested with the restriction endonucleases *Bam*HI, *Eco*RI, and *Hind*III in accordance with the directions of the manufacturer (New England Biolab, Beverly, Mass) as described previously.[21,22] Digested DNA was electrophoresed through 0.8% agarose gels and transferred to nylon filters (Gene-Screen Plus, New England Nuclear). Filters were hybridized overnight with ^{32}P-labeled nucleic acid probes containing 500 to 1,000 dpm/pg and washed at high stringency as outlined by the supplier. Autoradiograms were prepared by exposing filters to Kodak X-Omat AR film (Eastman Kodak Co., Rochester, NY) for one to seven days.

Nucleic acid probes. The C region was isolated from a T cell receptor β-chain cDNA YT35 (base pair [bp], 100 to 870, ref 2), by digestion with AvaI/PstI (C_β), and the 403-bp insert was subcloned into a pSP64 vector (Promega Biotec, Madison, Wis). Inserts were purified twice through low–melting point agarose and labeled with ^{32}P by random priming.

To detect Ig gene rearrangements, DNA probes of J_H, C_K, and C_λ were used as described.[21,22]

RESULTS

Characterization of the T_β gene in precursor T cell neoplasms. Restriction enzyme digestion with *Bam*HI and *Eco*RI and Southern blot analysis revealed frequent (14 of 16 cases) chain gene rearrangements in precursor T cell neoplasms (Table 1, Fig 1). In contrast, an Ig heavy-chain gene was rearranged in only one case, and Ig light chain genes were unrearranged in all T cell neoplasms. Only one of 30 B cell neoplasms contained T_β gene rearrangements (Fig 1). Rearrangements of the β-chain gene involved either a single allele (eight cases) or both alleles (six cases). Rearrangement of the second β-chain allele implies that T cell receptor gene rearrangements in these cells may be subject to error and require a second attempt at successful rearrangement, analogous to the mechanism used by B cells in the formation of functional Ig genes.[23]

A single restriction endonuclease, *Bam*HI, was sufficient to detect rearrangements in 13 of the 14 cases in which rearrangements occurred and, therefore, proved to be a useful enzyme for initial screening. It would be expected that *Bam*HI-digested DNA should show T_β gene rearrangements in most cases since the *Bam*HI restriction sites flank the entire $J_\beta1$-$C_\beta1$-$J_\beta2$-$C_\beta2$ complex, and the *Bam*HI restriction fragment would be altered by rearrangement involving either the $J_\beta1$ or $J_\beta2$ locus.[4] Additional rearrangements were detected with *Eco*RI in case 1, which showed no rearrangements with *Bam*HI, and in case 10, in which one rearrangement was detected with *Bam*HI and two with *Eco*RI. Presumably, rearranged bands obtained with *Bam*HI digestion comigrated with other bands on these blots. Demonstration of nongermline bands with *Eco*RI is indicative of a rearrangement of the $J_\beta1$-$C_\beta1$ complex, since the 12-kilobase (kb) *Eco*RI fragment encompassing this complex would be altered when $J_\beta1$ is involved in rearrangement. The 4-kb *Eco*RI germline fragment, which includes $C_\beta2$ but not $J_\beta2$, remains in the germline configuration regardless of the rearrangement of either the β1 or β2 complex.[24] No β-chain gene rearrangements were detected in two cases (2 and 3) despite digestion with *Bam*HI, *Eco*RI, or *Hind*III (Fig 2).

It should be noted that rearranged β-chain gene restriction fragment sizes differed from case to case. Therefore, it would appear that precursor T cell neoplasms may be using many different V_β genes and that no single common V gene is used as was previously suggested in a preliminary screening with *Eco*RI.[25]

Developmental association of phenotype and gene rearrangement. All cases, regardless of the occurrence of T cell receptor gene rearrangements, reacted intensely with the monoclonal antibody 3A1 and were unreactive with the B cell–associated antibodies B1 and B4. Thus, the 3A1+, B1−, B4− phenotype specifically distinguishes T and B cell precursor neoplasms since precursor B cell neoplasms are 3A1-negative[26] and react with antibodies B1 or B4.[27] Furthermore, the gene rearrangement studies presented here confirm that phenotypically defined precursor T cell neoplasms are uniformly 3A1+, B1−, and B4−.

Abbreviations: B, *Bam*HI; E, *Eco*RI; H, *Hind*III; G, germline; R, rearranged; RR, two alleles rearranged.

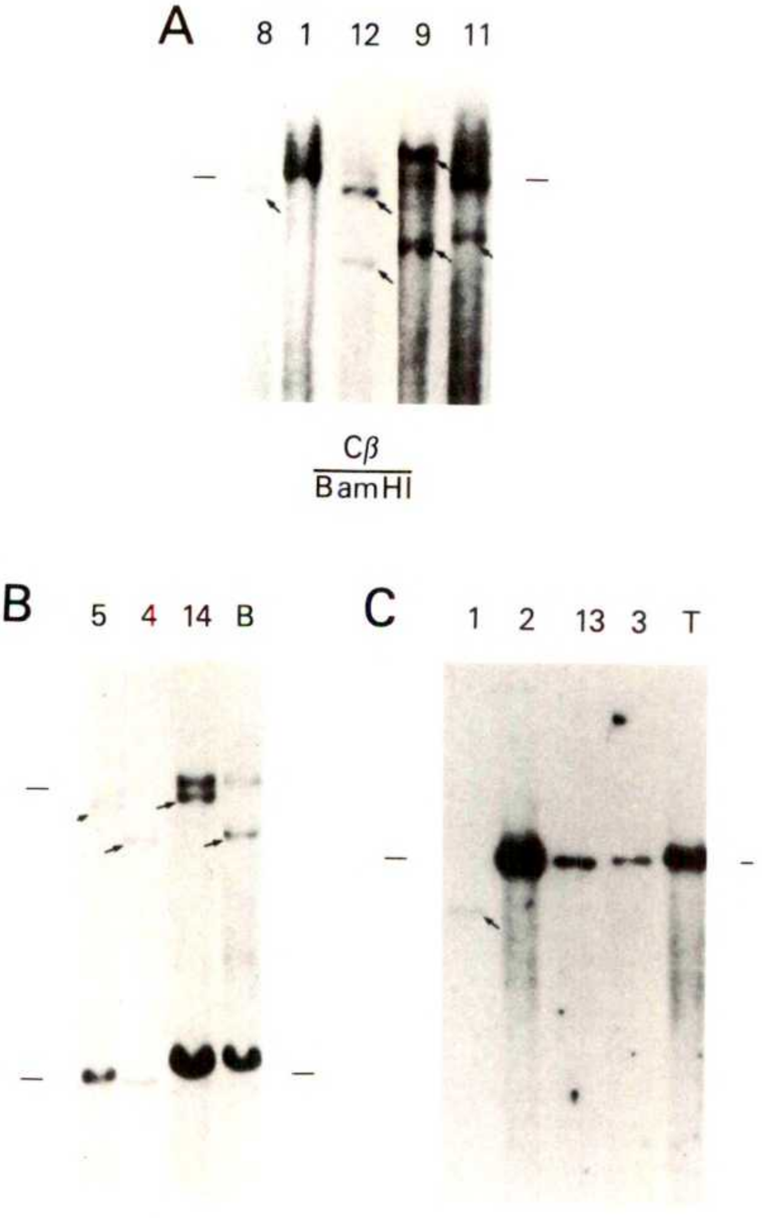

Fig 1. Gene rearrangements in precursor T cell neoplasms. Genomic DNA was digested with either *BamH*I (A) or *EcoR*I (B and C) and probed with the C_β cDNA (A and B) or a genomic probe of J_H (C). Lanes are labeled according to the case number presented in Table 1. Germline configuration of the genes is designated by a dash adjacent to the blot and rearrangements are shown by small arrows. In panel B the lane labeled B is a precursor B cell lymphoblastic leukemia, and in panel C for lane labeled T is normal human thymus as a control. A summary of the rearrangements is indicated in Table 1.

In contrast to the constant expression of the surface protein recognized by 3A1 in all cases, other molecules were selectively expressed. Surface T3 was expressed by seven of 15 cases tested and was preceded developmentally by T_β gene rearrangement, since rearrangements had occurred in all T3+ neoplasms and in six of eight T3− cases. It is known from studies of mutant T cell clones that the obligatory coexpression of T3 and the T cell receptor is contingent upon functional T cell receptor gene rearrangement and expression.[7] As a result, surface T3 is undetectable in the absence of T cell receptor gene rearrangement and expression. This fact, coupled with the requirement for T_β rearrangement prior to T3 expression presented here, would predict that T cell receptor surface expression in T cell neoplasms would adhere to the T3/T cell receptor coexpression rule.

A dissimilarity between precursor T cell neoplasms and normal cortical thymocytes is the expression of the sheep erythrocyte receptor or T11 molecule. This 50-kilodalton (kd) molecule, detected by monoclonal antibodies OKT11 and 9.6 (Lyt-3), is found on >95% of both cortical and medullary thymic lymphocytes.[1] However, six of 16 (37.5%) cases did not bear the T11 molecule, and included among these T11− cases are neoplasms with either rearranged or germline T_β genes.

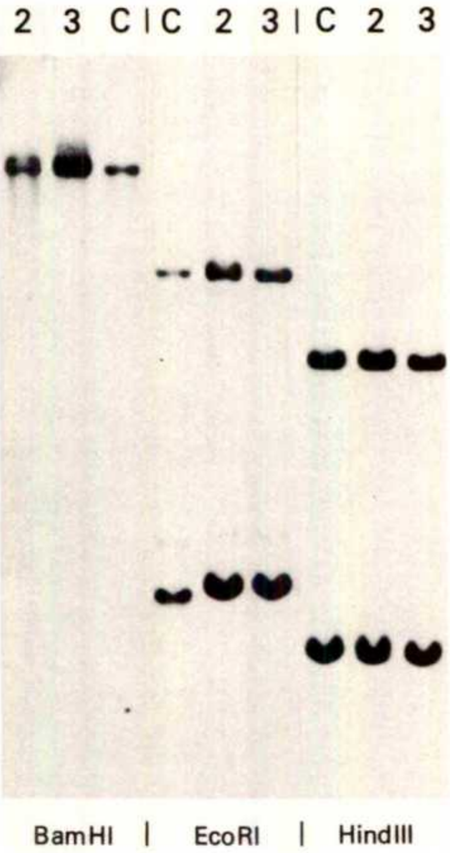

Fig 2. **Lack of T cell receptor β-chain gene rearrangements in two T lymphoblastic neoplasms. DNA from cases 2 and 3 and from a control (C, placenta) was digested with the indicated restriction enzymes and probed with the C_β cDNA fragment. No rearrangements of the β-chain gene were detected in either case 2 or case 3.**

DISCUSSION

By applying Southern blot analysis we found T_β gene rearrangements in most, but not all, precursor T cell lymphoblastic neoplasms. Rearrangements of the T_β gene were supportive of the T cell nature of these lymphoblastic neoplasms, since they only rarely occur in B cell neoplasms. In those instances where many conventional T cell–associated phenotypic markers were not expressed, T_β gene rearrangement analysis independently confirmed its T cell derivation. Another contribution of T_β gene analysis was the demonstration of monoclonality in T cell precursor neoplasms. Unlike B cells, T cells lack phenotypic markers for monoclonality, and therefore, the T cell receptor gene serves as a particularly useful parameter in the analysis of T cell lymphoproliferative disorders.[15–20]

Our gene rearrangement studies confirm that T_β gene rearrangements are not entirely restricted to T cells.[28,29] Lack of T_β rearrangements in most B cell neoplasms indicates that, despite close similarities in the organization of T_β and Ig gene recombination sequences, constraints governing rearrangement are generally regulated in a setting of T or B cell commitment. Out-of-context gene rearrangements of Ig heavy chain in malignant T lymphoblasts,[15,26,30,31] or T_β in B cell neoplasms, might represent isolated instances in which rearrangements occurred independently of lineage commitment and recombinatorial sequences from both genes were susceptible to the recombination mechanism. Rearrangements of both Ig heavy and light genes appear to occur specifically in B cells only.[21] It will be interesting to discover whether an analogous specificity is associated with T cell lineage, perhaps reflected by rearrangements of T_α and T_β genes.

T_β genes were retained in their germline, unrearranged organization in two of our T cell lymphoblastic neoplasms (Fig 2). Their T cell lineage was demonstrated by expression of 3A1 in both cases and T11 in case 2 and T1 in case 3. Neither showed any IgH gene rearrangements, and they did not express B1 or B4. Thus, these two cases appear to represent precursor T cells arrested at an immature stage of cortical thymocyte development prior to the onset of T_β gene rearrangement.

Expression of 3A1 by the two germline cases, as well as by all T lymphoblastic neoplasms having T_β gene rearrangements, underscores the importance of the use of 3A1 antibody for the identification of pre-T neoplasms.[13,32] 3A1 is not found on precursor B cell neoplasms[26] and, therefore, is a specific marker for the differential diagnosis of pre-T and pre-B neoplasia. 3A1 was the only marker expressed by all T cell lymphoblastic neoplasms in this series and in previous reports using either antibodies 3A1 or Leu-9, which apparently recognize the same surface molecule.[13] Significantly, these studies, as well as the present one, have shown that immature T cell neoplasms are often T11-negative. The frequency of T11– cases provides further support that a definition of precursor T cell neoplasms should not be restricted to T11+ cases but should encompass all 3A1+/Leu-9+ lymphoblastic leukemias and lymphomas.[13] The relatively common 3A1+, T11– precursor T cell neoplasm phenotype does not directly correlate with any of the known compartments of T cell differentiation, and when coexpression of other differentiation markers (T3, T4, T6, and T8) is taken into account, a rather broad range is represented by the 3A1+, T11– neoplasms (Table 1). Furthermore, T11 expression did not correlate with T_β gene rearrangement since both T11+ and T11– cases were found in either the presence or absence of rearrangements.

It has been suggested that the T11 molecule might be involved in triggering T_β gene rearrangement in T cell precursors,[33] but frequent absence of T11 in pre-T neoplasms implies that T11 is either transiently expressed or may be acquired after rearrangement has occurred. In this regard, the 40-kd surface polypeptide detected by antibody 3A1 might be considered a candidate surface molecule that plays a role in the development of rearrangements and their expression. However, 3A1/Leu-9 is not expressed by many cortical thymocytes or by 10% to 15% of mature T cells,[13,34] and its functional role awaits determination.

We have determined the pattern and occurrence of T cell receptor gene rearrangements in pre-T neoplasms and related these genetic findings to cellular phenotype. Precursor T cell neoplasms were found to encompass the earliest stages of T cell differentiation associated with the development of T_β gene rearrangements. Immunophenotypic and genetic characterization of this class of lymphoid neoplasia not only provides clues concerning their cellular differentiation but should also open new avenues for precise diagnosis and classification of T lymphoproliferative disease.

ACKNOWLEDGMENT

The authors gratefully acknowledge the gifts of YT35 cDNA from T. Mak and immunoglobulin gene probes from P. Leder. We thank E. Jaffe for continuing support and E. Sussman for technical assistance.

The Effect of Platelets in the Activation of Human Blood Coagulation Factor IX by Factor XIa

By Hans Soons, Truus Janssen-Claessen, H. Coenraad Hemker, and Guido Tans

We report here the effect of activated human platelets on the activation of human factor IX by human factor XIa. Factor IXa formed during activation was determined via its ability to activate bovine factor X. To increase sensitivity, phospholipids and bovine factor VIIIa were present in the assay. The kinetic parameters of the factor IX activation were determined in the presence of 10 mmol/L $CaCl_2$. The K_m for factor IX was 0.30 μmol/L and k_{cat} was 2.4 s^{-1}. Activated human platelets inhibited factor IX activation by factor XIa in a dose-dependent manner, whereas unstimulated platelets had no effect. Factor IX activation was inhibited for more than 90% at a platelet concentration of 4 × 10^8/mL, whereas concentrations of less than 10^8/mL had no influence. The inhibitory effect could be induced by thrombin, collagen, calcium ionophore A 23187, and adrenalin. The appearance of inhibitory activity could be blocked by the addition of the prostacyclin analogue ZK 36374 at any time during platelet activation. Stirring during platelet activation was not necessary. These results suggest that the inhibition is caused by a release reaction. This was confirmed by centrifugation experiments that showed that the inhibitory activity could be recovered from the supernatant of the activated platelets. The inhibitory activity was destroyed upon boiling and was susceptible to trypsin digestion. Passage of platelet supernatant over ACA 22 showed that the inhibitory activity eluted with an apparent molecular weight of less than 1,200,000 but greater than 669,000. The inhibition of factor XIa was reversible. These data suggest that platelets release an antiprotease of factor XIa that reversibly inhibits factor XIa. Lineweaver-Burk analysis showed that the inhibitor caused both an increase in K_m for factor IX and a decrease in k_{cat} of factor IXa formation by factor XIa.

HUMAN FACTOR IX is a vitamin K-dependent plasma protein that participates in the intrinsic pathway of blood coagulation.[1] It is present in plasma as a zymogen with a molecular weight (mol wt) of 57,000 daltons (d) at a concentration of 2.6 to 5.0 μg/mL. Human factor IX is converted to a serine protease, factor IXa, through proteolysis of two internal peptide bonds. This results in the release of an activation peptide (11,000 d) from the internal region of the precursor molecule. The resulting factor IXa (46,000 d) consists of a light chain (18,000 d) and heavy chain (28,000 d) held together by a disulfide bond(s).[2-3] Activation of factor IX in plasma can be accomplished by factor XIa[2-3] or by the factor VIIa-tissue thromboplastin complex.[4-5]

Platelets play an important role in blood coagulation. The platelet surface strongly promotes prothrombin and intrinsic factor X activation.[6] The activation of factor IX by factor XIa is one of the few reactions of coagulation for which no surface requirement is known. It has been suggested that collagen-stimulated platelets exhibit factor XIa-like activity, which can be determined in a clotting test.[7-8] However, others have failed to confirm this,[9] and it is not known whether factor XIa is involved. Up till now nothing is known about whether platelets have any effect in the activation of factor IX by factor XIa.

Several assays have been described in literature for the determination of factor IX activation: a coagulation assay in factor IX-deficient plasma,[10-12] a tritiated activation peptide release assay,[5,10,13] an immunoradiometric assay,[11] and an assay in which factor IXa is measured indirectly by determining the initial rate of factor X activation.[14] The most widespread used is the tritiated activation peptide release assay,[5,10,13] which was originally described for the activation of factor X by Silverberg et al.[15] In highly purified systems the appearance of factor IXa procoagulant activity follows the peptide release by a small lag period.[10] However, in less-purified systems, other enzymes may be present that give rise to similar peptide fragments but destroy the procoagulant activity of factor IX.[16] Therefore, to circumvent these potential difficulties, we have chosen to use an assay for factor IX activation by factor XIa, which detects the functional factor IXa activity via its ability to activate bovine factor X in the presence of phospholipids and $CaCl_2$.[14] To increase its sensitivity, bovine factor VIIIa was present. In that case, however, care has to be taken to add factor VIIIa under rigorously standardized conditions, since the assay is critically dependent on the amounts of factor VIIIa present.

This study was undertaken to explore the role of platelets in factor IX activation by factor XIa. We present evidence that platelets, upon stimulation, secrete an inhibitor that interferes with factor IX activation by factor XIa.

MATERIALS AND METHODS

Materials. Chromogenic substrates L-pyroglutamyl-L-prolyl-L-arginine-*p*-nitroanilide hydrochloride (S2337) and *N*-benzoyl-L-isoleucyl-L-glutamyl-(piperidyl)-glycyl-L-arginine-*p*-nitroanilide hydrochloride S2366 were purchased from A.B. Kabi Diagnostica, Stockholm. The prostacylin analogue ZK 36374 was a kind gift from Schering AG, Berlin. Plasma deficient in coagulation factors IX, XI, or XII were from patients congenitally deficient in these factors and were obtained from George King Biomedical, Overland Park, Kan. Hormon tendon collagen was obtained from Hormon-Chemi, Munich. Fatty acid-free human serum albumin and trypsin were from Sigma Chemical Co, St Louis. Two-milliliter plastic flat-bottom reaction tubes were obtained from Sterilin Ltd, Teddington, England; Teflon-coated magnetic stirring bars (7 × 2 mm) were purchased from Bel-Art Products, Pequannock, NJ. All reagents used were of the highest grade commercially available.

Proteins. Human factor IX was purified based on a modification of the isolation procedure described by di Scipio et al.[17] and the sulfated dextran column as described by Miletich et al[18] was added. Citrated fresh-frozen human plasma was thawed, and benzamidine

(10 mmol/L), heparin (6 mg/μL), and soybean trypsin inhibitor (10 mg/L) were added. The barium citrate absorption was followed by ammonium sulfate precipitations (40% and 70% saturation) before the vitamin K–dependent protein preparation was applied to a diethyl aminoethyl (DEAE)-Sephadex column followed by a heparin-Sephadex column.[17] Finally, a sulfated dextran column was used to purify factor IX.[18] Human factor IXa was prepared from purified human factor IX as described earlier for bovine factor IXa.[19] Human factor XI was purified according to Bouma et al.[20] Human factor XII was isolated as described by Griffin and Cochrane.[21] β-Factor XIIa was prepared from the purified human factor XII as described by Fujikawa and McMullen.[22] Bovine factor X was purified according to Fujikawa et al.[23] Bovine factor VIIIc was prepared as described earlier.[24] Factor VIIIa was prepared by activation of factor VIIIc (1.75 nmol/L) with thrombin (4 nmol/L) for one minute at 37 °C.[19,24] Bovine thrombin was purified as a prothrombin activation product as described by Rosing et al.[25] The specific activity of the thrombin preparation was 1 National Institutes of Health (NIH) U/mL = 11 nmol/L when a molecular weight of 35,600 was used for thrombin. The human factor IX, XI, and XII and the bovine factor X_1 and X_2 preparations were homogeneous and pure as determined by gel electrophoresis in the presence of sodium dodecyl sulfate on 10% gels according to Laemmli.[26] The specific activities of the protein preparation as determined with a clotting assay were 193, 211, 74, and 100 U/mg for human factors IX, XI, XII, and bovine factor X, respectively, assuming one unit of human factor IX, XI, and XII to be present per milliliter of human normal plasma and one unit of bovine factor X in one milliliter of bovine normal plasma. All proteins were stored at −70 °C after dialyzing against the following buffers: 50 mmol/L Tris-HCl, 175 mmol/L NaCl at pH 7.9 for human factor IX and bovine factor X; 4 mmol/L sodium citrate, 2 mmol/L acetic acid, 0.15 mol/L NaCl, and 0.5 mmol/L EDTA at pH 5.0 for human factor XI and XII; and 10 mmol/L morpholino ethane sulfonic acid, 175 mmol/L NaCl, 10 mmol/L $CaCl_2$, and 10% glycerol at pH 6.5 for bovine factor VIII. Trypsin was insolubilized by coupling trypsin (60 mg) in 0.1 mol/L $NaHCO_3$ to CNBr-activated Sepharose 4B (3 g) at 4 °C overnight according to the manufacturer's instructions.

Preparation of human factor XIa. Human factor XIa was prepared from human factor XI using human β-factor XIIa.[27] To 10 mL of factor XI (0.15 mg/mL) in 4 mmol/L sodium acetate, 2 mmol/L acetic acid, 0.15 mol/L NaCl, pH 5.0, was added 1.25 mL 0.5 mol/L Tris-HCl, 0.15 mol/L NaCl, pH 8.0, at 37 °C. Reaction was started by adding 1.27 mL β-factor XIIa (0.59 mg/mL) in 4 mmol/L sodium acetate, 2 mmol/L acetic acid, 0.15 mol/L NaCl at pH 5.0. Factor XI activation was followed by measuring factor XIa amidolytic activity. Activation was completed within 90 minutes. Factor XIa was separated from β-factor XIIa on a DEAE-Sephadex column (1.5 × 11.5 cm) at 4 °C in 50 mmol/L Tris-HCl and 150 mmol/L NaCl at pH 8.0. Factor XIa did not adhere to the resin, whereas β-factor XIIa was eluted by a linear salt gradient (0.1 to 0.5 mol/L) NaCl.

The amidolytic activity of human factor XIa was measured using the chromogenic substrate S2366 in a buffer containing 50 mmol/L Tris-HCl, 150 mmol/L NaCl, 20 mmol/L EDTA, and 0.5 mg/mL human serum albumin, pH 7.9. The kinetic parameters of S2366 hydrolysis by human factor XIa were K_m = 0.42 mmol/L and k_{cat} = 758 s^{-1}. k_{cat} was calculated using a concentration of factor XIa based on a mol wt of 160,000.

Protein concentrations. Determinations of protein concentrations were routinely done according to Bradford.[28] Factors IXa, Xa and thrombin were determined by active-site titration with p-NPGB-p-nitrophenyl-p′-guanidinobenzoate (p-NPGB) as described earlier.[14,25] Concentrations of factor IX and factor X were determined by complete activation and subsequent determination of the active enzyme. Factor VIIIa concentrations were determined according to the method of van Dieijen et al.[24] Factor XIa concentrations were determined from the amount of protein present assuming a mol wt of 160,000 d.[25]

Phospholipid vesicles. Phospholipid vesicles were made from a mixture of 40 mol/100 mL 1,2-dioleoyl-sn-glycero-3-phosphoserine (PS) and 60 mol/100 mL 1,2-dioleolyl-sn-glycero-3-phosphocholine (PC) in a buffer containing 50 mmol/L Tris-HCl and 175 mmol/L NaCl at pH 7.9 as described by Rosing et al.[25]

Collagen. Collagen was added in the nonfibrillar form, dissolved in acidic dilution buffer obtained from Hormon-Chemie as described by Rosing et al.[6] The minimal amount of collagen inducing aggregation and secretion was 1 to 2 μg/mL.

Factor IXa determinations. To follow the activation of factor IX by factor XIa an assay system was developed in which factor IXa was determined via its ability to activate bovine factor X in the presence of $CaCl_2$, phospholipid, and factor VIIIa. Factor IXa–containing samples were diluted in ice-cold buffer containing 50 mmol/L Tris (pH 7.9), 175 mmol/L NaCl, 0.5 mg/mL human serum albumin, and 20 mmol/L EDTA to block further activation of factor IX. The amounts of factor IXa present in the samples were then determined as follows. Three hundred five microliters buffer containing 50 mmol/L Tris (pH 7.9), 175 mmol/L NaCl, 9.8 mmol/L $CaCl_2$, 0.5 mg/mL human serum albumin, and 16.4 μmol/L phospholipid vesicles was prewarmed at 37 °C for 4½ minutes, after which 45 μL bovine factor X (16.67 μmol/L) and a 50-μL sample were added. Factor X activation was started by adding 100 μL factor VIIIa (1.75 nmol/L). The final reaction mixture (500 μL) contained 50 mmol/L Tris (pH 7.9), 175 mmol/L NaCl, 6 mmol/L $CaCl_2$, 2 mmol/L EDTA, 10 μmol/L phospholipid, 1.5 μmol/L factor X, 0.35 nmol/L factor VIIIa, 0.5 mg/mL human serum albumin, and the factor IXa present in the sample. The rate of factor X activation was determined by measurement of the amounts of factor Xa formed after one and two minutes in these reaction mixtures using the factor Xa–specific chromogenic substrate S2337 as described earlier.[14,19] From the observed rate of factor X activation, the amount of factor IXa present in the sample was calculated using a calibration curve made with known amounts of active-site titrated factor IXa (see also Fig 1).

Kinetic parameters. K_m for factor IX and k_{cat} of factor IX activation were determined by measurement of the rate of factor IXa formation in a reaction mixture containing 10 mmol/L $CaCl_2$, 0.5 mg/mL human serum albumin, 0.1 nmol/L factor XIa, and varying amounts of factor IX in HEPES buffer, pH 7.5, using the assay previously described. K_m and V_{max} (expressed as factor IXa formed per second) were then determined by statistical analysis of the data as described by Eisenthal and Cornish-Bowden.[29] k_{cat} was calculated by dividing V_{max} with the enzyme concentration assuming a mol wt of 160,000 for factor XIa.

Isolation of human platelets. Blood was drawn by venipuncture from healthy male volunteers who had not taken any medication for at least ten days. As anticoagulants, 1 vol of acid citrate dextrose (0.18 mol/L glucose, 0.08 mol/L trisodium citrate, and 0.052 mol/L citric acid) was added to 5 vol of whole blood. Platelet-rich plasma was obtained after centrifugation at 220 g for 25 minutes. Platelets were isolated by centrifugation at 1000 g for 20 minutes, and the pellet was gently resuspended in calcium-free HEPES buffer (10 mmol/L HEPES, 136 mmol/L NaCl, 2.68 mmol/L KCl, 2 mmol/L $MgCl_2$, and 5 mmol/L glucose), pH 6.7, containing 0.4% human serum albumin. The platelets were washed twice in this buffer by centrifugation at 600 g for 15 minutes. During the whole procedure except the last wash, acid/citrate/dextrose was present in the buffer (1 vol to 14 vol buffer).[30] Finally, the platelets were resuspended in HEPES buffer, pH 7.5, containing 0.1% human serum albumin. Platelet concentrations were determined with a Coulter counter

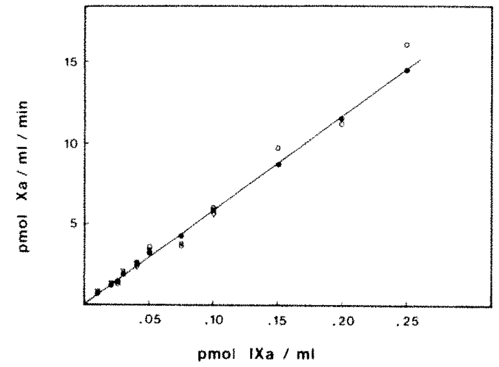

Fig 1. Factor IXa calibration curve. The rate of activation of bovine factor X (1.5 μmol/L) by varying amounts of factor IXa was determined in the absence (●) or in the presence of 3.2 × 10^7/mL stimulated platelets (▽) or their supernatants (○) at 37 °C in a reaction volume of 500 μL containing 50 mmol/L Tris (pH 7.9), 175 mmol/L NaCl, 6 mmol/L $CaCl_2$, 2 mmol/L EDTA, 10 μmol/L phospholipid vesicles (40% PS/60% PC, mole/mole), 1.5 μmol/L factor X, 0.35 nmol/L factor VIIIa, 0.5 mg/mL human serum albumin, and amounts of factor IXa as indicated in the figure. When stimulated platelets or their supernatants were present, factor IXa was preincubated with the platelets or their supernatant for four minutes at 37 °C prior to addition to the assay. Stimulated platelets were prepared by incubation at 37 °C for 12 minutes with 1.2 nmol/L thrombin, 10 μg/mL collagen, and 3 mmol/L $CaCl_2$ under continuous stirring. The supernatants were prepared by centrifuging the stimulated platelets for five minutes in an Eppendorf microfuge. For experimental details, see Materials and Methods under Factor IXa determination.

(Coulter Electronics, Luton, England) and were kept at room temperature.

RESULTS

Validation of the assay for factor IXa. In this study an assay for the activation of factor IX was used in which functional factor IXa activity was determined via the activation of bovine factor X as described earlier.[14] To increase its sensitivity, the activation of bovine factor X by human factor IXa was performed in the presence of $CaCl_2$, phospholipids, and bovine factor VIIIa. The amount of factor Xa formed was linear with time for at least two minutes (data not shown), and the rates of factor Xa formation were determined from the amounts of Factor Xa formed during these two minutes. Figure 1 shows that the rate of factor Xa formation was proportional to the amount of factor IXa added (closed circles). The slope of this plot reflects the rate of factor Xa formation per factor IXa present (59.5 nmol/Xa/min/nmol IXa). An excellent day-to-day reproducibility of the calibration curve could be achieved, since four separate experiments carried out at different days showed an SD of 1.7% in the slope of this plot.

This calibration curve was used in the experiments in which the activation of factor IX by factor XIa was determined. Since the experiments presented here concern the effect of platelets on the activation of factor IX by Factor XIa, the calibration curve was repeated in the presence of 3.2 × 10^7/mL thrombin/collagen-stimulated platelets (Fig 1, open triangles) or the supernatant thereof (Fig 1, open circles). As can be seen, the presence of the triggered platelets or their supernatants had no effect on the assay for factor IXa.

Factor IX activation by factor XIa. The assay just described was used to assess the kinetic parameters of factor IX activation by factor XIa in the presence of 10 mmol/L $CaCl_2$. It was verified that factor IX activation was linear with time and proportional to the amount of factor XIa used (data not shown). Varying concentrations of factor IX were incubated with factor XIa, and the rate of factor IXa formation was determined in the assay just described. Michaelis-Menten kinetics were observed throughout. The kinetic parameters were K_m = 301 nmol/L, and k_{cat} = 2.4 s^{-1} assuming a mol wt of 160,000 for factor XIa.

The effect of platelets in the activation of factor IX by factor XIa was studied. Nonstimulated platelets up to concentrations as high as 5 × 10^8/mL had no effect on factor IX activation. However, in the presence of platelets stimulated by the combined action of thrombin and collagen, the rates of factor IXa formation decreased with time until after two minutes a low rate of factor IXa formation remained (Fig 2). Preincubation of factor IX with the activated platelets for four minutes did not change the time course of factor IX activation. However, when factor XIa was preincubated with

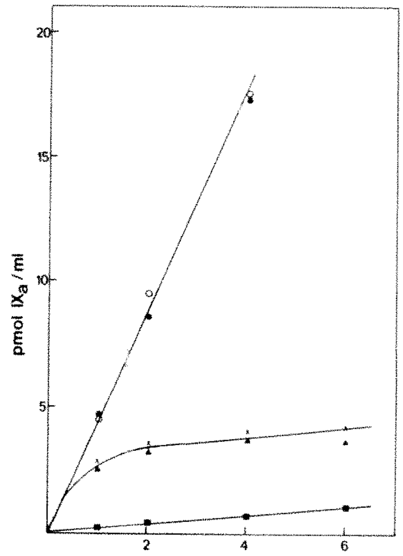

Fig 2. The effect of platelets in the activation of factor IX by factor XIa. The activation of factor IX (100 nmol/L) by factor XIa (0.1 nmol/L) was determined at 37 °C in the absence of platelets (○), in the presence of 5 × 10^8/mL unstimulated platelets (●), and in the presence of platelets (5 × 10^8/mL) that had been stimulated for 12 minutes at 37 °C under continuous stirring by thrombin (1.2 nmol/L), collagen (10 μg/mL), and 3 mmol/L $CaCl_2$ (X). The final reaction mixture contained 10 mmol/L $CaCl_2$, 0.5 mg/mL human serum albumin, 100 nmol/L factor IX, 0.1 nmol/L factor XIa, and 5 × 10^8/mL platelets in HEPES buffer at pH 7.5. At the time intervals indicated, samples were withdrawn and assayed for factor IXa as described in Materials and Methods. The points denoted (▲) were obtained after factor IX was incubated four minutes with the stimulated platelets prior to the addition of factor XIa. The points denoted by (■) were obtained after a four-minute incubation of factor XIa with the stimulated platelets prior to the addition of factor IX.

the triggered platelets, only the low rate of factor IXa formation remained. This strongly suggests that the inhibition was the result of a direct interaction with factor XIa that was completed within four minutes. Subsequent experiments showed that for platelet concentrations ranging from 10^6 to 10^9/mL a preincubation time with factor XIa of approximately ten minutes sufficed to result in linear rates of factor IXa formation. Therefore, in all subsequent experiments, factor XIa was preincubated for ten minutes with the platelets prior to the addition of factor IX.

The inhibitory effect of activated platelets at a suboptimal platelet concentration (4.10^7/mL) in factor IX activation by factor XIa was studied using different platelet agonists (Table 1). The most potent were thrombin (1.2 nmol/L), calcium ionophore A 23187 (1 μmol/L) and the combined action of thrombin (1.2 nmol/L) and collagen (10 μg/mL), whereas platelets activated by collagen (10 μg/mL) or adrenalin (546 μmol/L) caused a smaller inhibition. Platelets stimulated with adenosine diphosphate (ADP) (25 μmol/L) whether in the absence or presence of fibrinogen (0.7 mg/mL), showed no significant inhibition of factor IX activation by factor XIa under these conditions. Stirring of the platelets was not necessary to achieve the inhibitory activity.

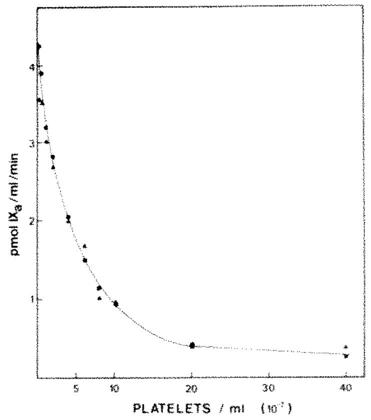

Fig 3. **Factor IX activation in the presence of varying concentrations of activated platelets or their supernatants. Varying amounts of platelets were stimulated for 12 minutes at 37 °C under continuous stirring with thrombin (1.2 nmol/L) and collagen 10 μg/mL) in the presence of 3 mmol/L $CaCl_2$. The platelets were then either incubated for an additional five minutes or centrifuged for five minutes in an Eppendorf Microfuge to obtain the supernatant. After this, the $CaCl_2$ concentration was adjusted to 10 mmol/L, and factor XIa was added and incubated for an additional ten minutes with the platelet suspensions or the supernatants. Subsequently, factor IX was added, and the rate of factor IXa formation was determined as described in Materials and Methods. The final reaction mixtures contained 10 mmol/L $CaCl_2$, 0.5 mg/mL human serum albumin, 100 nmol/L factor IX, and 0.1 nmol/L factor XIa in HEPES buffer (pH 7.5) and amounts of platelets (●) or their supernatants (▲) as indicated in the figure.**

Figure 3 shows that factor IX activation was inhibited in a dose-dependent way. Factor IX formation was not influenced at platelet concentrations less than 10^6/mL, and at higher platelet concentrations inhibition was observed until at a concentration of 4×10^8/mL factor IX activation was almost completely inhibited. During the platelet activation the lysis was always smaller than 2%. Lactic dehydrogenase (LDH) was taken as the parameter for platelet lysis. One hundred percent lysis was the amount of LDH measured when the platelets were sonicated. When the triggered platelet suspension was centrifuged, all the inhibitory activity was recovered in the supernatant (Fig 3), indicating that the inhibition is the result of platelet secretion upon triggering.

Table 1. The Effect of Different Platelet Stimulators in Factor IX Activation by Factor XIa

Trigger Substance	Rate of Factor IX Activation
No trigger	100%
ADP	95%
ADP/fibrinogen	92%
Adrenalin	84%
Collagen	84%
Thrombin	62%
A23187	58%
Thrombin/collagen	59%
Thrombin/collagen*	58%

*The platelets were activated by thrombin (1.2 nmol/L) and collagen (10 μg/mL) without stirring.

Platelets (4×10^7/mL) were incubated in HEPES buffer (pH 7.5) at 37 °C for 12 minutes in the presence of ADP (25 μmol/L), ADP (25 μmol/L), human fibrinogen (0.7 mg/mL), adrenalin (546 μmol/L), collagen (10 μg/mL), ionophore A23187 (1 μmol/L), thrombin (1.2 nmol/L), or thrombin (1.2 nmol/L), and collagen (10 μg/mL). During stimulation the platelets were stirred. After this incubation, factor XIa was added and incubated for ten minutes with the activated platelet suspension. The factor IX activation mixture contained 4×10^7/mL platelets, 100 nmol/L factor IX, 0.1 nmol/L factor XIa, and 10 mmol/L $CaCl_2$ in HEPES buffer, pH 7.5. Factor IX activation rates were determined as described in Materials and Methods and expressed as a percentage of the activation rate measured in the presence of unstimulated platelets (3.58 pmol IXa/min/mL).

The release of inhibition was studied using the prostacyclin analogue ZK 36374. This substance effectively blocks any further platelet aggregation[31] and platelet release reactions[32] when added to platelet suspensions (Fig 4). The addition of 100 nmol/L prostacyclin analogue prior to stimulation with 0.2 nmol/L thrombin effectively blocked any release of inhibitory activity. The time course of release of inhibitor was determined by the addition of ZK 36374 at various time intervals after the addition of thrombin to the platelets. The amounts of inhibitory activity released were then determined in the supernatant after centrifugation. Figure 5 shows that secretion of the inhibitor started after a small lag period of 10 seconds and reached a plateau after a platelet activation time of approximately four minutes.

Preliminary characterization of the inhibitory activity. To gain insight into the nature of the inhibitory activity secreted by platelets, the supernatant of a large amount of stimulated platelets (1.8×10^{10}) was collected, concentrated, and passed over a Sepharose ACA 22 column (2.5 × 85 cm). Figure 6 shows that the inhibitory activity was included in the column volume but eluted earlier than the largest mol wt marker available (669,000), thus precluding an accurate estimation of the apparent mol wt. The fractions of the column containing inhibitor were pooled and

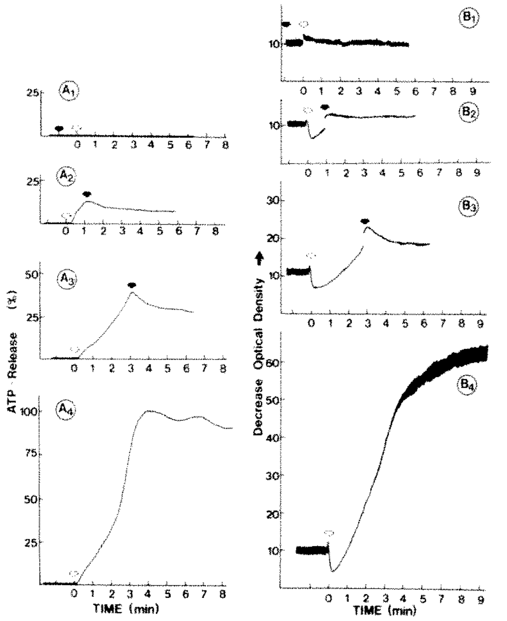

Fig 4. Influence of ZK 36374 on platelet aggregation and adenosine triphosphate (ATP) release. Platelet aggregation and ATP release were measured in an aggregometer. Washed platelets (2.3×10^8/mL) in HEPES buffer containing 2.6 mmol/L $CaCl_2$ and luciferin luciferase reagents were placed in the aggregometer under stirring conditions. At time 0, platelet activation was started by adding (0.7 nmol/L, ie 0.06 U/mL) thrombin (open arrow). At different time points, ZK 36374 (90 nmol/L) was added to stop the platelet activation (closed arrow). ATP release was monitored by luciferin-luciferase reaction (A), and platelet aggregation was measured at the same time (B). When ZK 36374 was added one minute before thrombin, no ATP release and platelet aggregation was measured (A_1 and B_1). When ZK 36374 was added one or three minutes after thrombin, ATP release and aggregation stopped immediately (A_2, B_2, and A_3, B_3). ATP release and platelet aggregation were also measured in the absence of ZK 36374 (A_4 and B_4). ATP release is expressed as a percentage, with ATP release in the absence of ZK 36374 taken as 100%.

concentrated, after which a part was treated with trypsin-Sepharose. Table 2 shows that no inhibitory activity remained after this treatment, whereas a control experiment with only Sepharose showed no loss of inhibitory activity. When the experiment with the trypsin-treated inhibitor was repeated in the absence of factor XIa, no activation of factor IX was observed, indicating that no significant amounts of trypsin were coming off the beads (data not shown). The inhibitor was also destroyed when placed in a boiling water bath for one hour. From these data we conclude that the inhibitor is a protein or contains a protein part essential for its activity that is susceptible to trypsin and is heat labile.

The data in Table 3 show that the inhibitor did not destroy or irreversibly inhibit factor XIa. When factor XIa was incubated with a high amount of inhibitor, only 21% of the rate of factor IX activation remained. However, when this incubation mixture was diluted fivefold, the rate of factor IX activation was only 1.6-fold less. Since rates of factor IX activation were linear with the amount of factor XIa present (see also the aforementioned), this indicated that some 50% of the factor XIa had become available again to participate

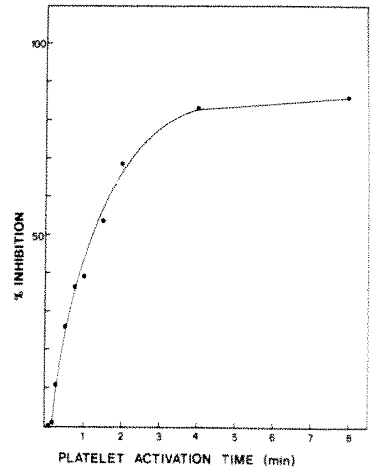

Fig 5. Time course of the appearance of inhibitory activity during platelet activation. Platelets (2.6×10^8/mL) were stimulated at 37 °C with thrombin (0.2 nmol/L) in the presence of $CaCl_2$ (3 mmol/L) under continuous stirring. At the time points indicated, the release reaction was blocked by adding the prostacyclin analogue ZK 36374 (100 nmol/L), and the platelet suspension was centrifuged for two minutes in an Eppendorf Microfuge to obtain the supernatant. After this, the $CaCl_2$ concentration was adjusted to 10 mmol/L, and factor XIa was added and incubated with the supernatant for 20 minutes at 37 °C, after which factor IX activation was started with the addition of factor IX. The final activation mixture contained 10 mmol/L $CaCl_2$, 0.5 mg/mL human serum albumin, 100 nmol/L factor IX, 0.1 nmol/L factor XIa, and supernatant of activated platelets (2×10^8/mL) in HEPES buffer. The rate of factor IX activation in the reaction mixture was determined as described in Materials and Methods and was expressed as a percentage of the factor IX activation rate measured in the presence of unstimulated platelets.

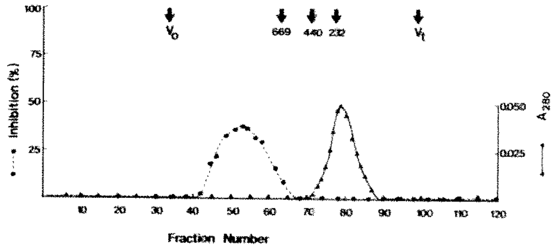

Fig 6. ACA 22 gel filtration on the supernatant of stimulated platelets. Platelets (1.15×10^9/mL) were activated in the presence of 3 mmol/L $CaCl_2$ with 1.2 nmol/L thrombin and 10 µg/mL collagen at 37 °C for 15 minutes in a total volume of 32.5 mL HEPES buffer (pH 7.5) containing 0.175 mg/mL human serum albumin. The supernatant was obtained by centrifugation for 20 minutes at 15,000 rpm in a Beckman J21 B and subsequently concentrated eightfold on a PM 10 filter (Amicon, Lexington, Mass). Two milliliters were applied to an ACA 22 column (2.5×85 cm) equilibrated in HEPES buffer (pH 7.5) at 4 °C. Elution was performed with the same buffer at a flow rate of 40 mL/h, and fractions of 4.5 mL were collected. Inhibitory activity was determined by incubating 450 µL of each fraction with 25 µL factor XIa (4nmol/L) for 15 minutes at 37 °C, after which 25 µL S2366 (5.8 mmol/L) was added and the rate of absorbance change at 405 nm recorded. The percentage of inhibitory activity was calculated from the amidolytic activity determined in the absence of inhibitor taken as 100%. Calibration of the column was achieved in a separate run using dextran blue 2000 (V_0), thyroglobulin (669,000), ferritin (440,000), catalase (232,000), and benzamidine (V_t).

Table 2. The Effect of Trypsin on the Activity of the Inhibitor in Factor IX Activation by Factor XIa

Activator	Rate of Factor IX Activation (pmol IXa/min/mL)
Factor XIa	3.97
Factor XIa, inhibitor	0.61
Factor XIa, inhibitor after incubation with Sepharose 4B	0.63
Factor XIa, inhibitor after incubation with trypsin-Sepharose	4.06

Human factor IX was activated by human factor XIa at 37 °C in HEPES buffer (pH 7.5) containing 100 nmol/L factor IX, 0.1 nmol/L factor XIa, 0.5 mg/mL human serum albumin, and 10 mmol/L $CaCl_2$ in the absence or presence of inhibitor. The rate of factor IXa formation was determined as described in Materials and Methods. Factor XIa was preincubated with inhibitor for 15 minutes at 37 °C before addition to the reaction mixture. The effect of trypsin on the inhibitor was determined by incubating 1.0 mL inhibitor with 0.25 mL trypsin-Sepharose slurry (or Sepharose 4B as a control) at 4 °C. After two hours, the suspension was centrifuged and the supernatant added to factor XIa to determine the residual inhibitory activity. The inhibitor preparation used was obtained from the ACA-22 column shown in Fig 6. Fractions 48 to 58 of this column contained inhibitory activity and were pooled. Human serum albumin, 2.5 mg, was added to the pool (44 mL), which was subsequently concentrated tenfold before use in the experiment described here.

in factor IX activation. The experiment in Fig 7 also illustrates this point. Here the time course of the disappearance of factor XIa amidolytic activity towards the chromogenic substrate S2366 was followed in an incubation mixture containing 0.4 nmol/L factor XIa and the supernatant of 2.2 × 10^8/mL activated platelets (closed squares). After equilibrium was reached, part of this mixture was diluted fivefold, and the remaining activity (expressed as a percentage of the amount of factor XIa present) was followed with time (closed circles). As can be seen, the amidolytic activity increased in the diluted mixture until the same final level was found as in a mixture that had been diluted fivefold at time 0 (closed triangles). Factor XIa activity was stable throughout the time course of the experiment in both the diluted and undiluted mixtures in the absence of platelet supernatant (open symbols). These data indicate that the inhibition of factor XIa was completely reversible.

Table 3. Effect of Dilution on the Activity of the Inhibitor in Factor IX Activation by Factor XIa

Activator	Rate of Factor IXa Formation (pmol IXa/min/mL)	
	Before Dilution	After Dilution
Factor XIa (0.1 nmol/L)	3.77	0.69
Factor XIa (0.1 nmol/L), supernatant of 2 × 10^8/mL platelets	0.80	0.49

Factor XIa (0.11 nmol/L) was incubated at 37 °C in HEPES buffer (pH 7.5) containing 1 mg/mL human serum albumin and 10 mmol/L $CaCl_2$ in the presence or absence of supernatant from 2.2 × 10^8/mL stimulated platelets (obtained as described in the legend to Fig 6). After 15 minutes, part of this mixture was diluted fivefold in the same buffer and further incubated at 37 °C for 30 minutes to allow reequilibration of factor XIa with inhibitor (see legend to Fig 7). After this time interval, factor IX activation in each of these mixtures was determined by the addition of factor IX so as to result in a final concentration of 100 nmol/L. Final concentrations of factor XIa and platelet supernatants reached are indicated in the table and were fivefold less in the diluted mixtures. The rate of factor IXa formation was then determined by withdrawing samples from these reaction mixtures at two and four minutes and assaying for factor IXa as described in Materials and Methods.

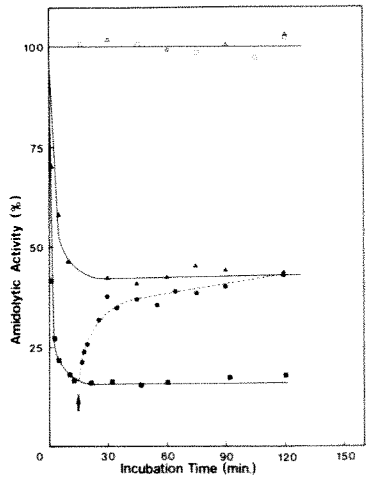

Fig 7. Reversibility of factor XIa inhibition. The supernatant (7.65 mL) of 2.6 × 10^8/mL platelets (obtained as described in the legend to Fig 5 was incubated for five minutes at 37 °C, and 0.9 mL factor XIa (4 nmol/L) was added. Immediately thereafter, 1.5 mL was subsampled and diluted fivefold in HEPES buffer containing 0.5 mg/mL human serum albumin. The time course of inhibition in each reaction mixture was followed by subsampling 475 μL to a cuvette at the time intervals indicated in the figure. Twenty-five microliters of S2366 (5.8 mmol/L) were added, and the rate of change of absorbance at 405 to 500 nm was determined at 37 °C on a DW2A Spectrophotometer (Amicon, Lexington, Mass). As a control, the amidolytic activity was followed over time in two reaction mixtures (prepared the same way) without supernatant present. The final concentrations in each reaction mixture were 0.5 mg/mL human serum albumin in HEPES buffer (pH 7.5): factor XIa (0.4 nmol/L), no platelet supernatant (□); factor XIa (0.4 nmol/L) and the supernatant of 2.2 × 10^8/mL platelets (■); factor XIa (0.08 nmol/L), no platelet supernatant (△); and factor XIa (0.08 nmol/L) and the supernatant of 4.4 × 10^7/mL platelets (▲). After equilibrium was reached, reversibility of the inhibition was verified by diluting part of the mixture containing the high concentrations of reactants fivefold and following the reappearance of amidolytic activity (●). The amidolytic activities determined for each reaction mixture in the presence of platelet supernatant were expressed as a percentage of the activities determined in the reaction mixture containing corresponding amounts of factor XIa but without supernatant present (open symbols).

Figure 8 shows Lineweaver-Burk plots of factor IX activation by factor XIa in the presence of varying amounts of platelet supernatant. These data show that both V_{max} and K_m were affected, indicating that the inhibitor is of the mixed type.

DISCUSSION

In this paper we report the effects of stimulated human platelets on the activation of human factor IX by factor XIa. We developed an assay that measures functional factor IXa via its ability to activate bovine factor X as described earlier[14] except that apart from phospholipids and $CaCl_2$ bovine factor VIIIa was also present in the assay. The

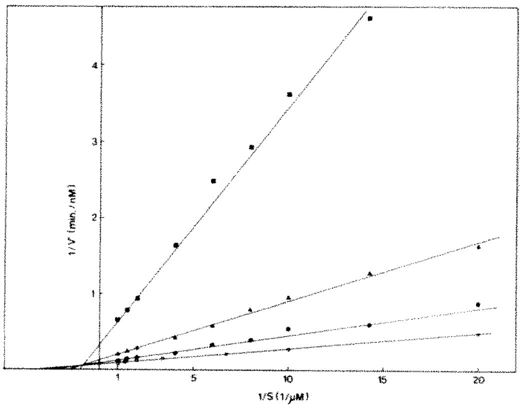

Fig 8. Lineweaver-Burk plots of factor IX activation by factor XIa at various inhibitor concentrations. The kinetic parameters (K_m for factor IX and V_{max}) were determined in the presence of varying amounts of inhibitor. Variation in the inhibitor concentrations was obtained by stimulating different platelet concentrations for twelve minutes at 37 °C in the presence of 3 mmol/L $CaCl_2$ with thrombin (1.2 nmol/L) and collagen (10 μg/mL) under continuous stirring followed by centrifugation for two minutes in an Eppendorf Microfuge to obtain the supernatants. Subsequently, the $CaCl_2$ concentration was adjusted to 10 mmol/L, and factor XIa was added and incubated for ten minutes at 37 °C before the addition of factor IX. The final reaction mixtures contained 10 mmol/L $CaCl_2$, 0.5 mg/mL human serum albumin, varying amounts of factor IX, and 0.1 nmol/L factor XIa in HEPES buffer (pH 7.5) without inhibitor (O) and in the presence of supernatant obtained from 2×10^7/mL platelets (●), 6×10^7/ml platelets (▲), and 2×10^8/mL platelets (■). Rates of factor IX activation were determined as described in Materials and Methods, and from these, the Lineweaver-Burk plots were constructed. The kinetic parameters obtained were 14.4 nmol/L factor IXa/min and 0.3 μmol/L (O), 10.0 nmol/L factor IXa/min and 0.37 μmol/L (●), 7.9 nmol/L factor IXa/min and 0.6 μmol/L (▲), and 3.0 nmol/L factor IXa/min and 0.99 μmol/L (■).

presence of factor VIIIa increases the sensitivity some 3,000-fold but has the disadvantage that for each new batch of factor VIII a new standard curve must be made. When this is done, a good day-to-day reproducibility can be achieved, and the assay allows accurate determination of factor IXa down to levels of 2.5 pmol/mL (Fig 1). Different batches of factor IXa, factor X, and phospholipid can be used interchangeably to produce the same standard curve provided equal amounts of these reagents are used. Using this assay, we determined the kinetic parameters of factor IX activation by factor XIa, and we found a K_m for factor IX of 0.3 μmol/L and a k_{cat} of 2.4 s^{-1}/factor XIa molecule of 160,000 mol wt. Some disagreement exists in the literature concerning these kinetic parameters. Walsh et al[10] using factor XIa activated with bovine factor XIIa found a K_m of 0.49 μmol/L and a k_{cat} of 7.7 s^{-1}, whereas Bajaj[13] using a trypsin-activated factor XIa found a k_m of 2.0 μmol/L and a k_{cat} of 0.34 s^{-1} (per 160,000 mol wt factor XIa). Both these studies made use of the tritiated activation peptide release. The kinetic parameters determined by us are rather close to the data reported by Walsh et al.[10]

Using this assay, we determined the effect of platelets on the rate of factor IXa formation by factor XIa. The data reported here clearly demonstrate that stimulated platelets cause a dramatic decrease in the rate of factor IX activation by factor XIa, whereas unstimulated platelets have no effect. This inhibition is caused by a direct interaction with factor XIa, since steady-state rates of factor IXa formation can only be achieved by incubation of factor XIa with the stimulated platelets, whereas preincubation of factor IX has no effect (Fig 2). Moreover, factor XIa amidolytic activity towards the chromogenic substrate S2366 is also inhibited (see Figs 6 and 7). Various platelet agonists can bring about this effect, the most potent being thrombin or the ionophore A23187. The set of agonists that can induce this effect (Table 1) as well as the rapid time course of the appearance of inhibitory activity after stimulation of the platelets (Fig 5) suggests the involvement of a release reaction. This is in accordance with the finding that the inhibitory activity is quantitatively recovered in the supernatant after centrifugation in a microfuge for five minutes (Fig 3). The amount of inhibitory activity is dependent on the amounts of stimulated platelets present. Thus, under the conditions used in our experiments, factor IX activation is not affected by the presence of 10^6/mL platelets. At the physiologic platelet concentration (2×10^8/mL), about 10% of the factor IX activation rate is left. Thus, the inhibitory activity reported here may play a role under physiologic circumstances. However, more experiments will be needed to gain insight into this.

The high apparent mol wt with which the inhibitor elutes from an ACA 22 column as well as the rather broad elution profile (see Fig 6) suggests that the inhibitor consists or is part of high-mol wt complexes. This may indicate that the inhibitor is associated with the so-called platelet dust.[33] However, an essential part of the large inhibitor molecules eluting from the ACA 22 column must be proteinlike in nature, since the inhibitory activity was completely destroyed after tryptic digestion. Moreover, the activity is also destroyed upon boiling. Therefore, at this moment we work under the hypothesis that the inhibitory activity is due to a protein that is released. This is most likely an antiprotease that reversibly blocks the factor XIa active sites both for factor IX activation and for S2366 conversion, since the inhibition seems reversible (see Table 3 and Fig 6). This inhibition is of the mixed type as determined by Lineweaver-Burk analysis of factor IX activation by factor XIa in the presence of varying amounts of inhibitor (Fig 8).

The main plasma inhibitors of factor XIa are α_1-antitrypsin and antithrombin III.[34] α_1-Antitrypsin is also present in platelets and can be secreted upon stimulation.[35] However, these inhibitors have a much lower molecular weight and irreversibly block factor XIa. Therefore, our data do not suggest any involvement of these proteins in the inhibition that we observe in our experiments. At this moment we do not know whether under different experimental conditions the α_1-antitrypsin present in platelets may become involved in the inhibition of factor IX activation by factor XIa.

It has been suggested that high-mol wt kininogen (HMWK) protects factor XIa against inactivation by plasma inhibitors,[34] and a recent report of Schmaier et al shows that HMWK can be secreted from human platelets upon stimulation.[36] The results presented here show that despite these amounts of HMWK present in the platelets the rate of factor IX activation by factor XIa decreases in the presence of stimulated platelets. Sinha et al have recently presented evidence that factor XIa needs HMWK to bind to stimulated platelets and that the amount of HMWK secreted by platelets is not sufficient to cause measureable factor XIa binding to triggered platelets.[37] Therefore, it will be important to investigate whether factor XIa binding via HMWK to stimulated platelets can prevent the inhibition of factor IXa formation caused by stimulated platelets in the absence of external HMWK.

ACKNOWLEDGMENT

We thank Dr Gerbrand van Dieijen for initiating this investigation. Dr J. Rosing and Dr J. van Wersch are acknowledged for valuable discussions. We would also like to thank T. Camphuisen for typing this manuscript.

A New von Willebrand Variant (Type I, New York): Increased Ristocetin-Induced Platelet Aggregation and Plasma von Willebrand Factor Containing the Full Range of Multimers

By Harvey J. Weiss and Ira I. Sussman

We report three members of a family who had reduced levels of plasma von Willebrand factor (vWF) and increased ristocetin-induced platelet aggregation (RIPA) (aggregation of platelet-rich plasma with ristocetin at a concentration of 0.45 mg/mL), as previously reported in type IIB and pseudo–von Willebrand's disease (vWD). However, in contrast to the latter two disorders in which the larger vWF multimers are absent in plasma, the entire range of vWF multimers was observed in the patients' plasma after sodium dodecyl sulfate–agarose gel electrophoresis, and all vWF multimers (including the largest) were present in the same proportion as in normal plasma and type I vWD. Thus, despite increased RIPA, the levels and multimeric pattern of vWF in this family's plasma were indistinguishable from those in type I vWD in which RIPA is usually decreased. Addition of ristocetin to the patients' platelet-rich plasma resulted in the removal of vWF (and, more selectively, of the large multimers) at lower concentrations of ristocetin than normal, as in type IIB and pseudo-vWD. The defect in the patients was localized to their vWF, which had an enhanced capacity for aggregating washed normal platelets in the presence of low concentrations of ristocetin and for aggregating pseudo-vWD platelets (in the absence of ristocetin). Both glycoproteins (GP) Ib and IIb-IIIa were involved in the enhanced aggregation response. RIPA (at low ristocetin concentrations) in the patients' platelet-rich plasma was abolished by a monoclonal antibody (AP1) to GPIb and was markedly reduced by monoclonal antibodies (10E5 and LJP9) that block adenosine diphosphate and thrombin-induced binding of vWF and fibrinogen to GPIIb-IIIa but was unaffected by an antibody (LJP5) that only blocks vWF binding. Partial inhibition of the initial aggregation slope (and complete inhibition of second phase aggregation) was achieved with creatine phosphate/creatine phosphokinase. EDTA blocked second-phase aggregation but was without effect on the initial slope. The findings in this family combine some features of both type I vWD (normal pattern of vWF multimers in plasma) and type IIB vWD (increased RIPA) and further demonstrate the increasing complexity of the structure-function relationships in vWD.

VON WILLEBRAND FACTOR (vWF) protein circulates in plasma as a series of multimers ranging in molecular weight (mol wt) from about 1 to 20 × 10^6 daltons.[1-5] Among its properties is the ability to bind to platelet glycoprotein (GP) Ib in the presence of ristocetin,[6-8] resulting in platelet aggregation.[9,10] One report has suggested that the larger multimers bind to GPIb with the highest affinity[11] and would therefore be the most effective in inducing ristocetin-induced platelet aggregation (RIPA), whereas others have found that the vWF monomer is comparable to that of the native protein.[12,13] The various plasma abnormalities in vWF that have been observed in patients with von Willebrand's disease (vWD) include a virtual absence of the protein (severe, type III vWD), a reduction in vWF but with all multimers present (type I vWD), or a selective absence of the larger multimers (type II vWD).[4,5,14] In type I and III vWD, RIPA is variably decreased in proportion to the reduction in plasma vWF,[10,15] and in most subtypes of type II vWD (such as IIA) in proportion to the decrease in the larger multimers.[16-19] However, a subtype of type II vWD has been described (type IIB) in which RIPA is increased despite the absence of the larger vWF multimers from the plasma.[4,5,19,20] In this disorder, platelet aggregation is observed with concentrations of ristocetin (0.3 to 0.6 mg/mL) that do not ordinarily produce aggregation in normal subjects.[19] It has been shown that the vWF in type IIB vWD binds more efficiently to platelets in the presence of low concentrations of ristocetin than does normal vWF[20] and that the larger multimers in these patients are also cleared more rapidly from plasma than in normal subjects.[21] Increased RIPA, associated with a loss of larger vWF multimers in plasma, is also characteristic of another disorder, pseudo-vWD[22] or platelet-type vWD,[23-25] in which the basic defect is not in the vWF protein but rather in the platelets, which have an enhanced capacity to adsorb vWF in the presence of low concentrations of ristocetin. The platelets of patients with pseudo-vWD were shown initially to aggregate directly with human vWF without the requirement for ristocetin,[22] and this was subsequently described in patients with platelet-type vWD as well.[24,25] In all likelihood, pseudo-vWD and platelet-type vWD are similar, if not identical, disorders.

We report herein a family with increased RIPA who do not appear to have any of the aforementioned variants of vWD. Unlike patients with type IIB vWD, the full range of vWF multimers (as in type I vWD) are present in their plasma. The increased RIPA was found to be due to an abnormal vWF rather than a platelet defect. Hence they do not have pseudo- (or platelet-type) vWD. They appear to have a previously undescribed subtype of vWD.

MATERIALS AND METHODS

Blood. Venous blood was mixed (9:1) with 3.2% sodium citrate and centrifuged to obtain platelet-rich plasma (PRP) and (platelet-poor) plasma as previously described.[10,15]

Bleeding time. The bleeding time was determined with a Simplate-II bleeding time device (General Diagnostics, Morris Plains, NJ).

Standard hematologic studies on plasma. Prothrombin time and partial thromboplastin time (PTT) were determined by standard techniques, and specific coagulation factors (factors VIII and XI) were assayed with reference to pooled normal plasma by a one-stage technique[15] using congenitally deficient plasmas as substrates.[15] vWF antigen (previously designated FVIIIR:Ag) was assayed by the Laurell electroimmunoassay (EIA) as previously described.[18] Ristocetin cofactor in diluted plasma was assayed using washed normal platelets and a ristocetin concentration of 1.25 mg/mL.[15]

Platelet studies. Platelets were counted by phase microscopy. Platelet aggregation induced in PRP by collagen, adenosine diphosphate (ADP), and epinephrine was studied in the aggregometer (Payton Associates, Buffalo) as previously described.[15] Aggregation by graded concentrations of ristocetin was determined by adding 20 μL of ristocetin (Lundbeck, Copenhagen) to 1.0 mL of PRP to achieve a final concentration ranging from 0.3 to 1.5 mg/mL. Results obtained were expressed as the initial slope of the aggregation curve (normalized to a chart speed of 20 mm/min) and as the maximal degree of aggregation.[15] vWF antigen in platelets was measured on lysates of washed platelets by EIA as previously described.[18,22] Platelet adhesion to rabbit subendothelium was measured by exposing deendothelialized segments of rabbit aorta to citrated whole blood[26] at a shear rate of 2,600 s^{-1} for five minutes.[27]

Special studies of vWF. Special studies on patient and normal vWF were performed using either plasma or various plasma fractions. Cryoprecipitate was prepared by thawing frozen (−70 °C) citrated plasma (prepared as previously described) for 16 hours at 4 °C.[22] Further separation of vWF was obtained by agarose gel chromatography. Cryoprecipitate, 1.7 to 2 mL, was applied to a 2½ × 30-cm column of agarose A-15m, and elution performed with 0.05 mol/L Tris-0.15 mol/L NaCl buffer, pH 7.1, as previously described.[28] vWF multimers were identified by electrophoresis of plasma or platelet lysates in 0.1% sodium dodecyl sulfate (SDS)–1.5% glyoxyl agarose according to the method of Hoyer and Shainoff.[1] Gels, 10 × 18 × 0.2 cm, were cast on gel bond film; 20-μL samples were electrophoresed to a length of 7 cm at a constant voltage of 100 V. The vWF multimers were visualized by autoradiography following incubation with ^{125}I-labeled rabbit antihuman vWF (RAH vWF). RAH vWF[28] was iodinated according to the iodogen method[29] and was purified on a 1 × 9-cm Sepharose 4B, vWF-affinity column that was eluted with 0.1 mol/L glycine, 0.5 mol/L NaCl, pH 2.8. Purification of vWF was performed as previously described.[28] The percentage of the total vWF represented by individual multimers was determined by densitometry. Scans of each gel were performed on a Quick Scan Jr (Helena Laboratories, Beamont, Tex) and the area under each curve determined by integration. The first six bands could be individually determined, whereas the areas under the remaining bands were grouped together. Each band was expressed as a percentage of the total area. Crossed immunoelectrophoresis was performed on 0.9%-agarose plates. Thirty-microliter plasma samples were electrophoresed at 200 V constant voltage in the first direction and 15 mA (two plates) constant current in the second direction. Precipitant arcs were visualized with either Coomassie blue dye or by autoradiography. In the latter, 100,000 cpm ^{125}I RAH vWF was added to the agarose gel in the second phase of the electrophoresis. The sialic acid content of highly purified vWF was determined by Dr Sandor Shapiro (Jefferson College, Philadelphia), as previously described,[30] from four to six units of plasma (1,000 to 1,500 mL) obtained by plasmapheresis, the latter kindly performed by Dr Randy Levine (St Luke's-Roosevelt Hospital Center). The ability of vWF in either plasma, cryoprecipitate, or vWF fractions to support aggregation of washed platelets was studied using platelets (from normal subjects) that had been separated from citrated PRP by albumin density gradient separation[22] and suspended in calcium-free Tyrode's buffer (pH 7.3) at a final platelet count of 300,000 to 1,200,000/μL as previously described.[22] Adsorption of plasma vWF to platelets in the presence of ristocetin was performed as previously described.[22] For these studies, a suspension of washed platelets was incubated with an equal volume of plasma in the presence of various concentrations of ristocetin for 30 minutes at 37 °C, and after centrifugation at 2000 g for ten minutes, the supernatant plasmas were frozen at −70 °C until studied. The vWF antigen in the supernatant was assayed by radioimmunoassay,[31] (kindly performed by Dr Leon Hoyer, University of Connecticut Health Science Center, Farmington) and vWF multimers were determined as described previously.

Platelet inhibitors. The inhibitory effects of several monoclonal antibodies to platelet GP on RIPA was studied by the addition of these antibodies to PRP. A previously described[32] monoclonal antibody (AP1) against platelet GPIb that blocks ristocetin-induced binding of vWF to platelets[32] was kindly provided by Drs Robert Montgomery and Thomas Kunicki (Blood Center of Southeastern Wisconsin, Milwaukee). A monoclonal antibody (10E5) against GPIIb-IIIa was a gift from Dr Barry Coller (State University of New York, Stony Brook). This antibody has been previously shown to block the binding of fibrinogen to thrombin and ADP (but not ristocetin)-stimulated platelets[33] and, more recently, has been shown to block the binding of vWF, fibronectin, and thrombospondin as well.[34] Several other monovalent Fab fragments of monoclonal antibodies against GPIIb-IIIa were a gift of Dr Zaverio Ruggeri (Scripps Clinic and Research Foundation, La Jolla, Calif). Antibody LJP9 inhibits the thrombin and ADP-induced binding to GPIIb-IIIa of both vWF and fibrinogen.[35] Antibody LJP5 inhibits the binding of vWF but not fibrinogen,[35] and antibody LJP10 binds to BPIIb-IIIa without inhibiting uptake of either vWF or fibrinogen (Dr Z. Ruggeri, personal communication). A possible role for ADP was studied using PRP prepared from blood anticoagulated (9:1) with 3.2% sodium citrate containing 90 mmol/L creatine phosphate and 60 U/mL creatine phosphokinase (CP/CPK) (Sigma Chemical Co, St Louis). The effect of adding Na_2 EDTA was also studied. The studies using CP/CPK, EDTA, and monoclonal antibodies 10E5 and LJP9 were performed at concentrations of these substances that completely abolished platelet aggregation by 20 μmol/L ADP.

Patients. Three members of a family with a mild bleeding history were studied. Patient 1, the propositus, is a 24-year-old male who reported a lifelong history of easy bruising. He bled excessively after a tonsillectomy at age 2½ and received plasma transfusions as treatment for a trauma-induced hematoma in his leg at age 13. However, he did not bleed excessively after a herniorrhaphy at age 1½ yrs. His twin sister (patient 2) also bruises easily, bled excessively after a tonsillectomy at age 2½, and at age 16 received blood transfusions for treatment of a large, painful hematoma on the buttocks. A second sister, aged 29, was not studied but is said to bruise easily and had life-threatening hemorrhage after a tonsillectomy at age 4. In addition, she suffered a hemarthrosis of the right ankle at age 23 (for which she received cryoprecipitate) and, in the same year, was treated with fresh-frozen plasma for about ten days after right knee surgery complicated by bleeding and the development of an anterior compartment syndrome. The 48-year-old mother of the propositus (patient 3) bled extensively after tooth extractions and postpartum, had one episode of unexplained gastrointestinal bleeding, and has received both plasma and cryoprecipitate for treatment of bleeding episodes. Patient 1 was studied by us on multiple occasions, and patient 2 was studied twice. Samples of frozen plasma on patient 3 (in whom variably depressed, but sometimes normal, levels of vWF and factor XI have been found elsewhere) were kindly provided in June 1985 by Dr Judith Ratzan of Miami. The second affected sister of the propositus was not studied but has been diagnosed elsewhere as having vWD (with a normal factor XI level).

Other subjects. Control subjects were normal hospital personnel, aged 21 to 50. Patients with type I vWD included those with decreased levels of vWF in plasma and platelets, which we have previously designated as type I-1 vWD, and those with decreased plasma but normal platelet vWF levels (type I-2 vWD[18]).

RESULTS

Basic hematologic studies. Patients 1 and 2 were studied in our laboratory, and selected studies on patient 3 were done on samples of frozen plasma. Normal values were obtained for hemoglobin, white blood count, prothrombin time, and platelet count. Other studies are shown in Table 1. The bleeding time (performed once) was within the range of normal values. Factor VIII:C and vWF values on the propositus (patient 1) were obtained on four separate occasions. The average value obtained for Factor VIII:C was 26 U/dL; for vWF antigen, 38 U/dL; and for ristocetin cofactor, 41 U/dL. The relatively concordant decrease in these values is characteristic of the findings in type I vWD. The values of factor VIII:C, vWF antigen, and ristocetin cofactor obtained in his twin sister (patient 2) and mother (patient 3) were, in most cases, just at or somewhat below the lower limits of the control values (Table 1). The overall findings in the three affected family members studied suggest a diagnosis of type I vWD with variable degrees of penetrance. Since the vWF antigen in their platelets was normal (Table 1), they have the subtype of von Willebrand's disease that we have previously designated as type I-2.[18] In addition to the aforementioned findings, factor XI was moderately decreased in patients 1 and 3 (40 and 34 U/dL, respectively) and was at the lower limit of normal in patient 2 (60 U/dL).

†Performed elsewhere.

‡Control values obtained on eight to 13 normal subjects.

In patients 1 and 2, average results shown for plasma values and ristocetin aggregation are for studies obtained on four and two separate days, respectively.

RIPA. On all occasions studied, the addition of ristocetin to the PRP of both patients 1 (four occasions) and 2 (two occasions) resulted in platelet aggregation (60% to 91%) at concentrations (0.45 and 0.60 mg/mL) that never produced aggregation in normal subjects (Fig 1 and Table 1). This enhanced response to ristocetin is typical of previous findings in type IIB[4,5,19,20] and pseudo-[22] or platelet-type vWD.[23-25] No aggregation resulted upon the addition of either cryoprecipitate or vWF fractions to patient PRP (data not shown), nor was spontaneous aggregation observed.

Multimeric structure of vWF. Figure 2 shows the multimer pattern of vWF in representative plasma samples for the three family members (patients 1, 2, and 3), three control subjects (N1, N2 [father of the propositus], N3), and three patients with typical type I vWD (two with type I-1 and one with type I-2). The full range of vWF multimers was consistently present in all three patients; their multimer patterns were indistinguishable from those in control plasmas or in patients with type I vWD. These patterns were observed in plasma samples obtained from patient 1 on four different days at intervals of 4, 2, and 2 months, from patient 2 on two samples obtained 1 week apart, and on one sample of plasma from patient 3. The conclusions drawn from visual examination of the gels were confirmed by densitometric scan in that the percentage of the total vWF contributed by the larger multimers (those of mol wt greater than band 6), as well as by all other multimers, were the same in the three affected family members as in the controls or type I subjects (Table 2). The pattern of vWF multimers in their platelets was also normal (data not shown).

Enhanced capacity of patient vWF to support ristocetin aggregation. Several types of studies were done that demonstrated that the enhanced RIPA in the affected family members was due to an abnormality in their plasma vWF. In one group of studies, platelet aggregation induced by increasing concentrations of ristocetin was assessed in a mixture containing washed normal platelets and either cryoprecipitate (at a final vWF antigen concentration of 35 U/dL) or

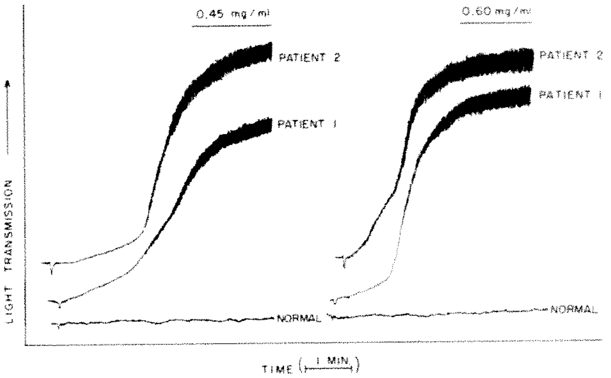

Fig 1. **Aggregation of patients' PRP by low concentration of ristocetin. Ristocetin was added to citrated PRP in a concentration of 0.45 or 0.60 mg/mL. Results are shown for patients 1, 2, and a typical normal subject. For complete dose-response data, see Table 1.**

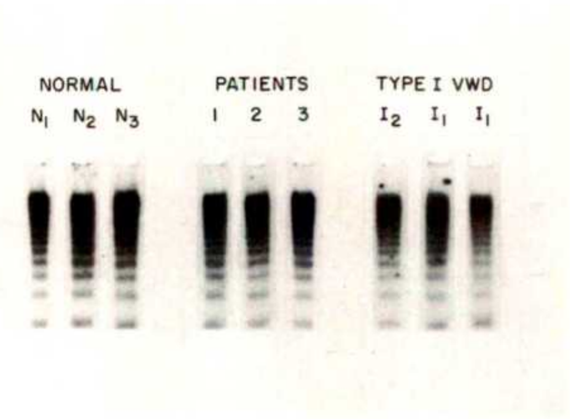

Fig 2. Multimeric composition of plasma vWF. Autoradiographic pattern of plasma vWF multimers detected by ^{125}I-labeled anti-vWF after electrophoresis in SDS–glyoxyl agarose. The anode is at the bottom. Studies are shown for patients 1, 2, 3, for three normal subjects (N1, N3, and N2, the father of patients 1 and 2), and for three patients with type I (two with I-1 and one with I-2) vWD. The percentage of the total vWF for each of the first six multimers and for the multimers of mol wt greater than band 6 is shown in Table 2.

plasma (at a final vWF antigen concentration of 20 U/dL). The enhanced capacity of cryoprecipitate from patient 1 to support RIPA at low concentrations of ristocetin is shown in Fig 3A and 3B. Similar studies using plasma are shown in Fig 3C and demonstrate the enhanced capacity of vWF from patients 1, 2, and 3 to support RIPA when compared with plasmas from normal subjects or from patients with either type I-1 or type I-2 vWD. The experiment was modified by using, instead of a fixed concentration of vWF, increasing concentrations of vWF and a fixed, low concentration (0.6 mg/mL) of ristocetin. The enhanced capacity of vWF from patient 1 to support platelet aggregation by a low concentration of ristocetin is shown in Fig 3D. Finally, the increased reactivity of patient vWF with platelets in the absence of ristocetin was demonstrated using PRP from a subject with pseudo-vWD. We have previously shown that platelets from these patients are aggregated by human vWF without a requirement for ristocetin.[22] The enhanced capacity of vWF from patients 1 and 2 to induce platelet aggregation in a patient with pseudo-vWF is shown in Fig 4.

Table 2. Densitometric Scan of vWF Multimers in Plasma

	Percentage of Total vWF*								
	Normal			Patients			Type I vWD		
Multimer No.	N1	N2	N3	1	2	3	I-2	I-1	I-1
>6	60	53	58	56	55	57	56	55	58
6	6	8	7	7	7	6	6	8	6
5	7	8	6	8	8	7	7	6	6
4	7	9	9	9	8	8	8	9	7
3	6	7	6	7	8	9	7	7	6
2	6	8	7	7	8	6	7	7	7
1	6	7	7	7	7	7	9	9	10

*The percentage of the total vWF for bands 1 (the multimer of lowest mol wt) through band 6 and for the vWF accounting for all multimers with mol wt > band 6, determined by densitometric scan of the gels shown in Fig 2.

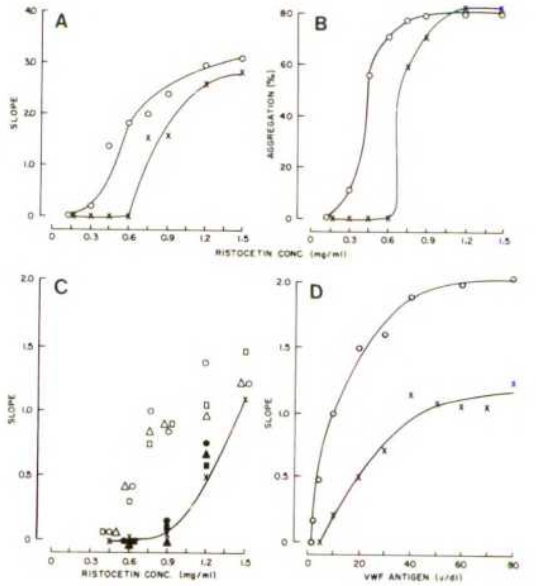

Fig 3. Capacity of vWF to support ristocetin-induced aggregation of washed normal platelets. Platelet aggregation induced by 10 μL of ristocetin was studied in a mixture containing a suspension of albumin density gradient, washed normal platelets and plasma, cryoprecipitate, or fractions prepared from the latter. (1) Top: initial slope (A) or aggregation (B) in a mixture containing 240 μL platelet suspension + 250 μL cryoprecipitate (in Tris-saline, pH 7.3, to a vWF concentration of 70 U/dL) from patient 1 (○) or a control (X) and increasing concentrations of ristocetin. (2) Bottom left (C): 240 μL platelet suspension + 250 μL of pooled normal or patient plasma containing 0.1 units of vWF antigen (achieved, where necessary, by dilution with type III vWD plasma) plus increasing concentrations of ristocetin. The initial slope is shown for normal subjects (X); patients 1 (○), 2 (△), and 3 (□); and patients with type I-1 (●, ■) and I-2 (▲) vWD. (3) Bottom right (D): 140 μL washed platelets and 350 μL of a vWF fraction diluted in Tris-saline to contain variable amounts of vWF + ristocetin (final concentration 0.6 mg/mL). The initial slopes obtained with increasing (final) concentrations of vWF antigen are shown for patient 1 (○) and a normal control (X).

Increased adsorption to platelets of vWF and of the larger vWF multimers from patient plasma in the presence of ristocetin. In these studies, increasing concentrations of ristocetin were incubated at 37 °C. for 30 minutes with a mixture containing equal volumes of washed normal platelets and plasma from either a normal subject or patient 1. The final vWF antigen concentration in the mixture without ristocetin was 20 U/dL, obtained in the case of the normal subject by prior dilution with plasma from a patient with severe (type III) vWD. After centrifugation, the vWF antigen content in the supernatant was measured by radioimmunoassay, and the percentage of vWF antigen remaining (not adsorbed to platelets) was calculated with reference to a control incubation mixture. In addition, the multimer pattern of vWF in each supernatant sample was determined. Figure 5 demonstrates the enhanced ristocetin-induced adsorption of vWF and the larger vWF multimers observed with the plasma of patient 1. In contrast to this abnormality of plasma vWF, the capacity of the patient's platelets to adsorb normal vWF with increasing ristocetin concentrations was the same as in normal platelets (data not shown).

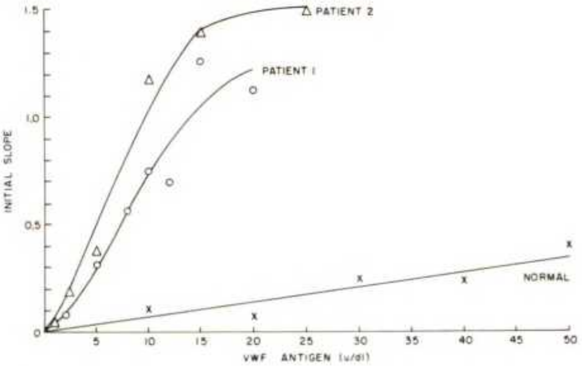

Fig 4. **Aggregation of platelets of a patient with pseudo-vWD by plasma. Plasma from patients 1, 2, or a normal control were mixed, when necessary, with plasma from a patient with type III (severe) vWD to achieve varying concentrations of vWF antigen, and 0.5 mL was added to an aggregometer cuvette containing 0.5 mL of PRP from a patient with pseudo-vWD[22] whose platelets are aggregated directly by vWF without a requirement for ristocetin. The figure shows the initial slope of the aggregation tracings.**

Sialic content of vWF. The sialic content of highly purified vWF was the same (98.3 nmol/mg protein) as in a control subject studied in parallel (89.7 nmol/mg protein). Both of these values are somewhat lower than in previous normals studied in the laboratory of Dr Sandor Shapiro (131 ± 16 nmol/mg protein).[30] The reason for this is not clear but could be related to the fact that because of the limited sample only one, rather than two, cryoprecipitations were used in the present study and this could have resulted in a vWF preparation of somewhat lesser purity.

Crossed immunoelectrophoresis. The precipitin arc of vWF obtained by crossed immunoelectrophoresis of plasma from patient 1 was of the same configuration as that observed in the plasma from a normal subject or from a patient with type I vWD (data not shown).

Effect of platelet inhibitors and monoclonal antibodies to platelet GP on RIPA. PRP from patient 1 was used in the study, and the results are summarized in Fig 6. Platelet aggregation by 0.6 mg/mL ristocetin was completely blocked by a monoclonal antibody (API) to GPIb.[32] The initial slope of the aggregation tracing was markedly diminished by two different monoclonal antibodies (10E5 and LJP9) that block thrombin and ADP-induced binding of vWF and fibrinogen to GPIIb-IIIa.[33-35] In contrast, no inhibitory effects on RIPA were observed with either monoclonal antibody LJP5, which blocks thrombin-induced binding of vWF, but not fibrinogen, to GPIIb-IIIa,[35] or with antibody LJP10, which binds to GPIIb-IIIa but does not inhibit the binding or any known protein. The effects of several known platelet inhibitors were also studied. EDTA (0.1%) had no effect on (and may have even enhanced) the initial response (slope) to ristocetin, but it abolished secondary aggregation. The ADP-removing system CP/CPK inhibited the initial slope and abolished secondary aggregation.

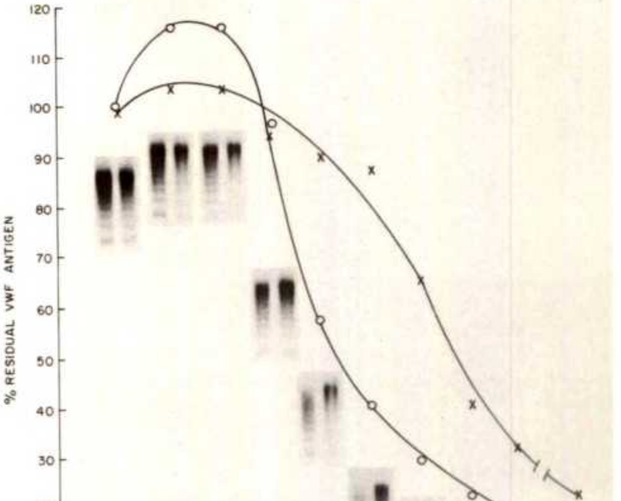

Fig 5. **Adsorption of plasma vWF to normal washed platelets in the presence of ristocetin. A suspension of washed normal platelets (500 μL) was incubated with an equal volume of plasma (vWF antigen content, 40 U/dL) from patient 1 (O) or a normal subject (X) and adjusted to the same vWF antigen concentration by dilution with plasma from a patient with severe (type III) vWD in the presence of increasing concentrations of ristocetin for 30 minutes at 37 °C without stirring. After centrifugation, the supernatant plasma was assayed for vWF antigen by radioimmunoassay, and the amount of vWF adsorbed to platelets was calculated with reference to a control specimen in which platelets and ristocetin were omitted (no platelets). The vWF multimer patterns shown for each supernatant (patient, left; control, right) demonstrate the more selective removal of the larger vWF multimers from the plasma of patient 1 with increasing concentrations of ristocetin.**

Platelet adhesion to subendothelium. Platelet adhesion to subendothelium, studied in citrated blood at a shear rate of 2,600 s^{-1}, was normal in both patients 1 and 2 (58% and 55% *v* control values of 42% ± 5%). To study specifically the properties of patient vWF in supporting adhesion, we added increasing concentrations of normal or patient vWF (in cryoprecipitate) to samples of citrated blood from a patient with severe (type III) vWD and then studied platelet adhesion to subendothelium. When compared at comparable levels of vWF antigen, the ability of patient vWF to correct the adhesion defect in type III vWD was, if anything, somewhat greater than that observed with normal vWF (data not shown).

DISCUSSION

Except for the enhanced platelet aggregation of their platelets by low concentrations of ristocetin, many of the findings in the family reported herein are those of type I vWD. Thus, factor VIII:C and vWF-related properties,

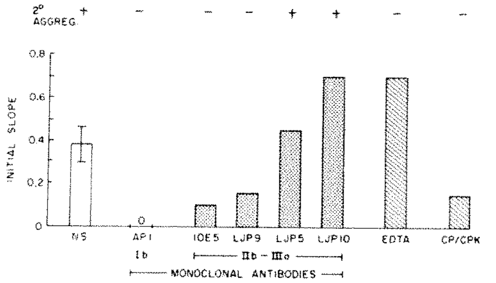

Fig 6. Effect of monoclonal antibodies to platelet GP and platelet inhibitors on platelet aggregation by a low concentration of ristocetin. To 940 μL of PRP from patient 1 was added the following substances and, where necessary, normal saline (NS) to a final volume of 980 μL and the final concentrations indicated: (1) 0 to 35 μL normal saline, n = 4; (2) 40 μL of a monoclonal antibody (AP1) to GPIb, 4 μg/mL, (3) monoclonal antibodies to GPIIb-IIIa as follows: 20 μL 10E5, 10 μg/mL; 5 μL LJP9, 50 μg/mL; 10 μL of LJP5, 50 μg/mL; and 20 μL of LJP10, 100 μg/mL; (4) 20 μL EDTA, 0.1%; or (5) 980 μL of PRP prepared from blood anticoagulated with sodium citrate containing CP/CPK (see Materials and Methods). After the addition of 20 μL of ristocetin (final concentration, 0.6 mg/mL), platelet aggregation was determined. The figure depicts the value of the initial aggregation slope (including the range for the four control samples) and the presence (+) or absence (−) of secondary aggregation following the initial aggregation response.

particularly in the propositus (patient 1), were decreased concordantly, and the complete range of vWF multimers was observed in their plasma (Fig 2). In addition, the proportion of the larger multimers to the total vWF was the same as in normal subjects and patients with typical type I vWD (Fig 2 and Table 2), thereby distinguishing this family from patients designated as type I B[36] in whom the larger multimers are present, but decreased in amounts relative to the other multimers. We have previously identified other subtypes of type I vWD according to the content of vWF antigen in plasma and platelets.[18] In the subtype designated I-1, the amount of vWF antigen in both plasma and platelets was decreased, whereas platelet vWF antigen was normal in type I-2. Findings entirely similar to these have recently been reported by Mannucci et al.[37] The family described herein had normal levels of vWF antigen in their platelets (Table 1) and hence has type I-2 vWD according to our nomenclature. Neither we nor others have ever observed enhanced RIPA in type I vWD, and specifically, we did not observe this in two recently studied unrelated patients with the type I-2 subtype. Previously, an increase in RIPA has been described in only two disorders, type IIB vWD[4,5,19,20] and pseudo-[22] or platelet-type vWD,[23,24,38,39] in both of which the larger vWF multimers are absent in plasma. Since the family reported herein has a type I plasma vWF multimer pattern, they cannot be classified as having either of these two disorders. However, as in type IIB-vWD, the defect was clearly localized to an abnormality in their vWF rather than in their platelets (as is the case in pseudo- or platelet-type vWD). Similar to the findings in type IIB vWD,[20] their vWF had a greater capacity for supporting platelet aggregation by low concentrations of ristocetin than vWF from normal subjects or from three patients with more typical type I vWD (Fig 3). In addition, patient vWF was more effective than normal vWF in aggregating the platelets of a patient with pseudo-vWD (Fig 4), demonstrating that the enhanced reactivity of their vWF towards platelets can be demonstrated in the absence of ristocetin. By analogy with type IIB, it might be appropriate to designate these patients as having type IB vWD, but since this term has already been used for another subtype of type I,[36] we have chosen to designate our family as having vWD type I–New York or, alternatively, type IV vWD.

The basis for the enhanced capacity of the vWF in patients with vWD type I–New York to support platelet aggregation by low concentrations of ristocetin remains to be determined. As in type IIB vWD,[19,20] this enhanced aggregation was associated with increased adsorption to platelets of vWF and, more specifically, of the larger vWF multimers (Fig 5), which may bind to GPIb with the highest affinity.[11] Not surprisingly, platelet aggregation by low concentrations of ristocetin was completely blocked by a monoclonal antibody to GPIb since aggregation by ristocetin requires, initially, the binding of vWF to this platelet membrane GP.[6–8,40–42] Aggregation by low concentrations of ristocetin was also greatly diminished by monoclonal antibodies to GPIIb-IIIa (10E5 and LJP9) that block ADP- and thrombin-induced binding of vWF and fibrinogen to this membrane GP,[33,35] but was not inhibited by antibody LJP5, which only blocks vWF binding.[35] These findings together with the inhibitory effect of the ADP-consuming system CP/CPK suggest that the binding to GPIIb-IIIa of fibrinogen (but not vWF) through endogenous platelet ADP may also contribute to the enhanced RIPA in vWD type I–New York. These conclusions are consistent with recent studies that have demonstrated that the binding of fibrinogen to GPIIb-IIIa plays a role in the aggregation of normal platelets that is initiated by binding of vWF to GPIb.[43,44] The enhanced initial response to low concentrations of ristocetin in the presence of EDTA (which blocks binding of proteins to GPIIb-IIIa[5]) may be related to the fact that calcium is not required for the initial binding of vWF to GPIb[8] and suggests that this binding may even be enhanced in vWD type I–New York.

Several aspects of this disorder remain to be clarified. For one, it is not clear why, as in type IIB vWD, the larger multimers are more selectively removed from plasma by low concentrations of ristocetin, yet (unlike type IIB) the native plasma contains the full range of multimers (and the same proportion of larger multimers as in normal plasma). In theory, an increased clearance of larger multimers from plasma, as in type IIB vWD,[21] could be compensated for by increased synthesis, but we have no evidence to support this possibility. The relationship of the abnormal vWF in vWD type I–New York to the bleeding disorder in this family is also not entirely clear. Platelet adhesion (in citrated blood) to subendothelium was not diminished in these patients under conditions that have demonstrated decreased adhesion in patients with severe vWD,[26] although we have not systematically studied patients with milder forms of type I vWD. However, we found no evidence to suggest that the vWF in type I–New York is deficient in its capacity to support platelet adhesion, and in fact, where this was specifically examined, vWF type I–New York appeared to correct the platelet adhesion defect in severe vWD to a greater extent than normal vWF. An interpretation of the findings in this study is further complicated by the somewhat decreased factor XI values in two members of the family, although this was normal in one other clinically affected family member (patient 2) and was said to be normal in a second severely affected sister of the propositus who was not studied by us. In all likelihood, the bleeding disorder in the family is probably the result of low to marginal levels of vWF and factor VIII:C, and in some cases, factor XI, which are unable to support normal hemostasis under some circumstances. The findings in the present study demonstrate further the evolving complexity of the clinical and laboratory findings in vWD and demonstrate the problems involved in attempting to define the disorder in terms of either the plasma multimer patterns or functional studies such as those involving ristocetin aggregation. The family designated as having vWD type I–New York in the present study has features of both type I vWD (multimer patterns) and type IIB vWD (enhanced ristocetin aggregation) and underscores the desirability of assigning, ultimately, subtypes on the basis of the molecular defects in the vWF protein.

NOTE ADDED IN PROOF

We recently studied patient 3 in our laboratory and, on freshly drawn blood specimens, obtained values as follows: platelet aggregation 61% at a ristocetin concentration of 0.6 mg/mL, Factor VIII: C = 64 U/dL, Factor XI = 65 U/dL, vWF antigen = 52 U/dL, and ristocetin cofactor = 50 U/dL. Platelets, 305,000/μL; bleeding time, 7 min.

Nonrandom Distribution of Iron in Circulating Human Transferrin

By Olga Zak and Philip Aisen

By combining the urea gel electrophoresis technique of Makey and Seal with Western immunoblotting, a method has been developed for analyzing the distribution of iron between the two sites of circulating human transferrin. The new method avoids exposure of samples to a nonphysiologic pH that may promote removal or redistribution of iron from the protein; this facilitates examination of multiple samples at one time. Analysis of 21 freshly drawn specimens from normal human subjects confirms previous reports that iron is not randomly distributed in the specific sites of transferrin. Rather, there is a considerable range in the ratio of occupancies of N-terminal and C-terminal sites (N:C ratio), from 0.31 to 6.87 in the present study, with the N-terminal site predominantly occupied in most subjects. The N:C ratio correlates modestly with serum iron concentration ($r = .54$). Possible flaws in studies indicating a random occupancy of the specific sites of circulating transferrin may lie in the low pH to which samples may be exposed during procedures based on isoelectric focusing or in drawing inferences from data considering only total monoferric transferrin rather than the two distinguishable monoferric species.

© *1986 by Grune & Stratton, Inc.*

DIFFERENCES between the two iron-binding sites of human serum transferrin have been revealed by a wide variety of thermodynamic,[1-3] kinetic,[4] and spectroscopic[1,5-7] measurements. However, studies of the functional properties of the two distinguishable sites carried out in vitro in attempts to elucidate any physiologic roles of these differences have led to inconsistent results.[8-11] Clearly, if the sites are unequally populated in the circulation, then differences in their physiologic behavior in vivo must also exist. Previous investigations bearing on this question have led to conflicting findings. Methods using urea gel electrophoresis have generally shown that the sites are not equally populated,[12,13] the more weakly binding B-site in the N-terminal domain of the protein being predominantly occupied. Another study using isoelectric focusing in polyacrylamide gels to resolve the four possible species of transferrin of varying content (iron-free or apotransferrin, monoferric transferrin bearing its iron atom at the C-terminal or A-site, monoferric transferrin occupied at the N-terminal or B-site, and saturated or diferric transferrin) has also indicated that iron is nonrandomly distributed between the binding sites of circulating transferrin.[14] However, a recent report, also based on isoelectric focusing, has suggested that iron is randomly distributed, implying that the two sites are equally occupied whatever the level of iron saturation.[15] Because of the importance of the site occupancies in achieving understanding of the molecular physiology of iron transport, we have reexamined the problem using procedures designed to minimize the redistribution of iron in samples exposed to a nonphysiologic pH[1,13,16] or stored under conditions in which migration of iron may be favored.[13,16] Our present findings reinforce earlier inferences from studies in this laboratory[1] and by Williams' group.[13,16] Additionally, we report possible pitfalls in the collection and analysis of data in studies based on isoelectric focusing.[15]

MATERIALS AND METHODS

Transferrin

Human serum transferrin was isolated from a 40% to 75% ammonium sulfate fraction of blood bank plasma by chromatography with diethylaminoethyl (DEAE)–Sephadex A-50 (Pharmacia Fine Chemicals, Piscataway, NJ) following previously detailed procedures.[1] Preparations were freed of iron, then brought to the desired degree of saturation by the addition of appropriate quantities of freshly prepared ferrous ammonium sulfate. The absorbancy at 280 nm of millimolar apotransferrin was taken as 86.6.

Reagents and Buffers

Reagent grade chemicals were used for all preparations. Buffers for electrophoresis were passed through a column of Chelex-100 (Bio-Rad Laboratories, Richmond, Calif) to minimize contamination with extraneous metal ions. Ampholyte (pH 5 to 8) was obtained as 40% Ampholine from LKB (Gaithersburg, Md), acrylamide and bisacrylamide were purchased from Eastman Kodak (Rochester, NY) and other reagents from standard laboratory suppliers. Doubly distilled, deionized water was used in all preparations, and glassware was acid washed.

Collection of Blood Specimens

Samples of venous blood from normal human volunteers were collected in acid-washed tubes and allowed to clot for no more than 1½ hours under Parafilm caps at room temperature before removal of serum. After this time the pH of the serum differed by less than 0.01 units from the pH of serum obtained from preparations clotted in a 5% CO_2 incubator. Because we have verified the observations of Williams and Moreton that storage of serum at ordinary freezer temperature promotes redistribution of iron to the C-terminal site of transferrin,[13] all samples were analyzed immediately after collection.

Electrophoretic Methods

The classical urea gel electrophoresis technique of Makey and Seal,[17] widely adopted for studies of iron occupancy of the two sites of transferrin,[18] has been modified for the present work. Because of the finding that higher than physiologic pH favors binding of iron at the N-terminal site of transferrin,[16] we have substituted a 0.089 mol/L Tris-acetate buffer at pH 7.4 for the pH-8.4 Tris-borate buffer in the original Makey-Seal procedure. Electrophoresis was initiated at an electric field of 20 V/cm, gradually increased to 30 V/cm, then continued for a total of 550 V h/cm. This resulted in separation of the four molecular species of transferrin with resolution comparable to that obtained with the original Makey-Seal procedure.

Gels of purified transferrin preparations were stained with Coo-

massie blue following standard procedures. For analysis of serum samples, autoradiograms of Western blot preparations were made using the Bio-Rad Trans-Blot cell, largely following the methods of Burnette.[19] Urea gels were washed twice, for ten minutes each time, with ice-cold 0.02 mol/L barbital buffer, pH 8.6, then three times with transfer buffer consisting of 0.192 mol/L glycine, 0.025 mol/L Tris, and 10% methanol at pH 8.8. Electrophoretic transfer of proteins from gel to nitrocellulose paper was carried out in a cold room for 1½ hours at 100 V followed by 2½ hours at 50 V. Nitrocellulose paper bearing the transferred protein was washed for one hour in a buffer of 0.9% NaCl, 0.01 mol/L Tris, 0.1% bovine serum albumin, and 0.05% Tween 20, then for an additional four hours (or overnight) in a buffer containing 1% bovine serum albumin but no detergent. To display transferrin bands, autoradiography was carried out with nitrocellulose sheets that had been incubated with affinity-purified, ^{125}I-labeled rabbit antibody to human transferrin. This antibody gave single lines of identity between purified transferrin and human serum by the double-diffusion technique of Ouchterlony. The Western blot method proved simpler and more readily applicable to the study of multiple serum specimens (Fig 1A) than the previously used crossed immunoelectrophoresis procedure.[12]

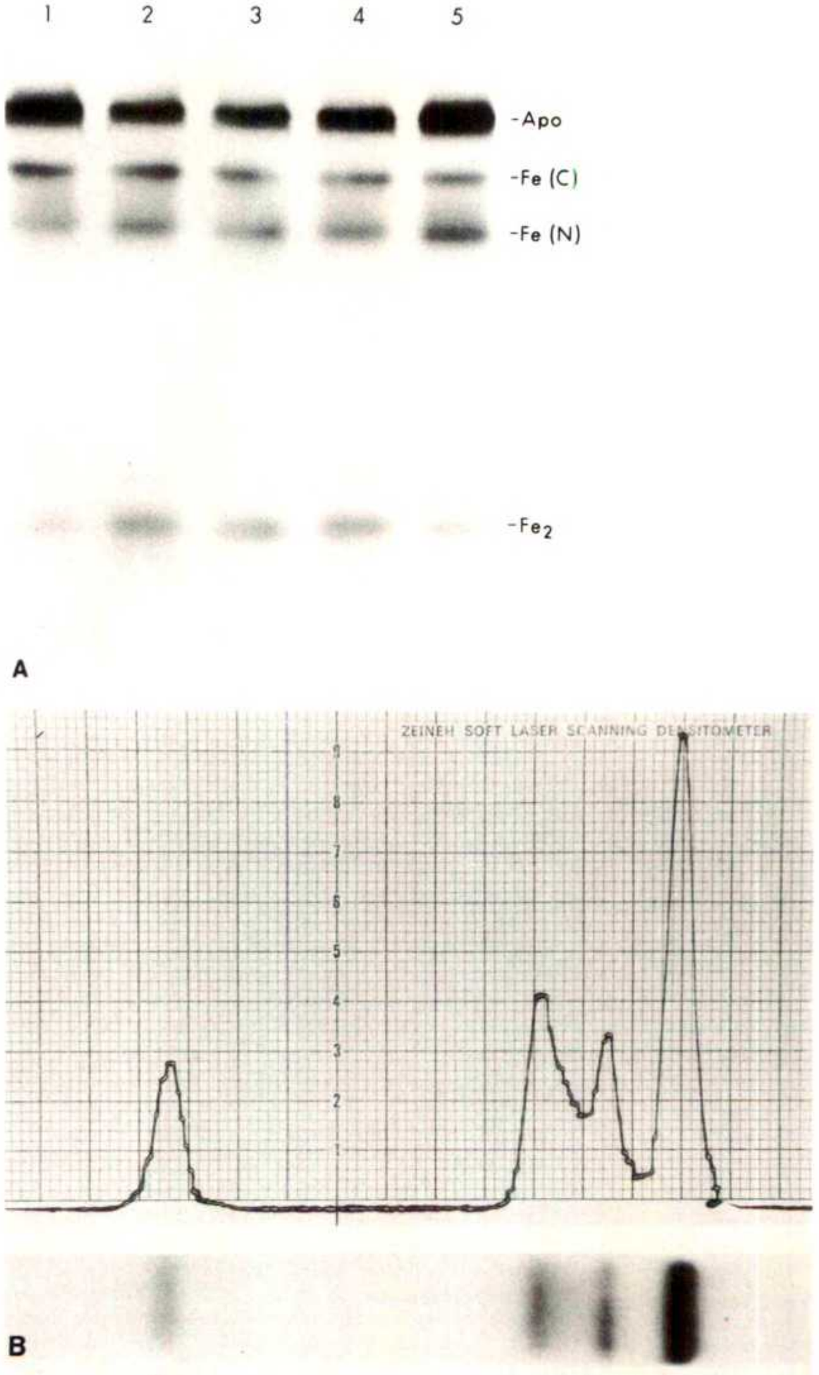

Fig 1. Analysis of transferrin species in human serum by Western blotting. (A) Five different serum samples with N:C ratios of 0.79 (lane 1), 1.08 (lane 2), 1.32 (lane 3), 1.27 (lane 4) and 2.24 (lane 5). (B) Densitometric scan of a serum sample showing an N:C ratio of 1.89.

Relative proportions of transferrin species in Coomassie blue–stained gels and Western blot autoradiograms were evaluated with a laser scanning densitometer (Biomed Instruments, Fullerton, Calif) after the procedures of Chasteen and Williams[16] (Fig 1B). Five scans at uniform spacing across each lane were taken for each sample and the results averaged to minimize errors from a nonuniform distribution of protein across lanes.

For isoelectric focusing the methods given by Huebers and co-workers[15] were followed as closely as possible.

Iron Analyses

Determinations of serum iron concentrations and saturations were performed with Sigma kits (Sigma Chemical Co, St Louis) according to the manufacturer's instructions.

RESULTS

Validation of Present Methods

Efficiency of transfer in Western blots. To evaluate the completeness of protein transfer from gel to nitrocellulose paper during the Western blot procedure, gels were stained with Coomassie blue following electrophoretic transfer. No protein bands could be seen, indicating that transfer from the gels was complete.

Standard curves. A series of eight transferrin solutions varying in saturation from 0% to 100% was prepared. Standard curves relating saturation estimated from densitometry to actual saturation gave a satisfactory linear relationship (Fig 2). Results from Western blot scans agreed with results from Coomassie blue stains of preparations run in parallel but not transferred from gel to nitrocellulose paper. Apotransferrin and saturated transferrin each gave single bands by urea gel electrophoresis, demonstrating that neither contamination of preparations with extraneous iron nor removal of specifically bound iron from transferrin had occurred during the urea gel electrophoresis procedures.

Reproducibility and constancy over time of serum samples. Two samples of different sera, both run in triplicate in each of two separate gels, yielded ratios of N-terminally occupied monoferric transferrin to C-terminally occupied monoferric transferrin (N:C ratio) of 1.63 ± 0.05 and 2.33 ± 0.18. Thus, the reproducibility of the Western blot method appears to be better than ±10%.

Four samples of blood were obtained from one volunteer throughout a period of eight hours. The N:C ratios ranged from 1.06 to 1.22, indicating little diurnal variation in this individual.

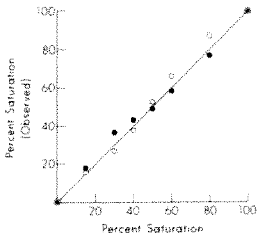

Fig 2. Observed *v* actual transferrin saturations in purified transferrin preparations. ○, Coomassie blue stains; ●, Western blots.

Analysis of Serum Samples

In a series of 21 serum samples from normal volunteers, the ratio of N-terminal monoferric transferrin to C-terminal monoferric transferrin ranged from 0.31 to 6.87 (Fig 3). In 16 subjects this N:C ratio exceeded unity, ranging from 1.06 to 6.87. In five subjects the N:C ratio was less than unity, ranging from 0.31 to 0.79. These subjects tended to have lower levels of serum iron (60 ± 24 μg/dL) than did those subjects with N:C ratios greater than unity in whom the mean serum iron levels were 110 ± 35 μg/dL. Linear regression analysis also indicates a direct, albeit modest, correlation between the serum iron concentration and N:C ratio ($r = .543$).

Studies of Isoelectric Focusing

Preparations of apotransferrin, 50% saturated transferrin, and fully saturated transferrin were examined by isoelectric focusing in polyacrylamide tube gels. None of these preparations gave single or simply interpretable bands (Fig 4). In contrast, urea gel electrophoresis yielded single bands for apotransferrin and diferric transferrin and a four-band pattern for half-saturated protein. One possibility to account for the multiplicity of bands in saturated transferrin is that the protein is partially depleted of iron by the low pH (5.0 to 5.4) at which it electrofocuses. In support of this possibility, we have observed that saturated transferrin in 2% Ampholine at 2 °C loses 25% of its absorbance at 470nm within 15 minutes. This accords with the finding of Surgenor and colleagues, reported nearly 40 years ago,[20] that transferrin relinquishes specifically bound iron below pH 6.3.

DISCUSSION

The N:C ratio measures the relative occupancies of the two sites of transferrin in the circulation, thereby affording a

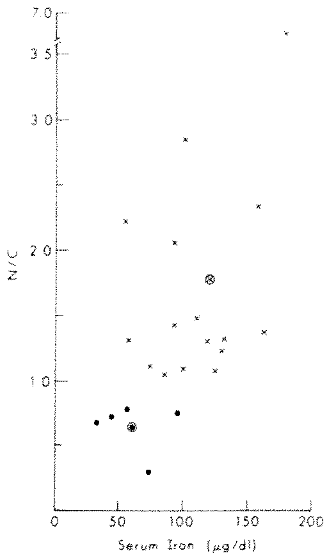

Fig 3. Scatter plot of N:C ratios in 21 normal human serum samples. ●, samples with N:C less than unity; ×, samples with N:C greater than unity. Circled points indicate mean values for each set.

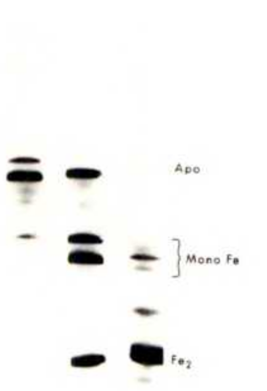

Fig 4. Isoelectric focusing patterns of purified transferrin preparations at indicated saturations with iron. Gels are stained with Coomassie blue.

measure of the apparent affinities of the two sites of the protein for iron[1] in the living organism. For this reason we have expressed our results in terms of this ratio rather than as the equivalent but perhaps less revealing form giving the percentages of total monoferric transferrin in the N and C states. The mean value of the N:C ratio for all subjects tested is 1.60. Accordingly, the binding of iron to circulating transferrin is neither randomly determined, in which case the N:C ratio must be unity, nor thermodynamically governed, for then the N:C ratio must be close to 0.2.[1] Evidently the differential occupancies by iron of the two sites of circulating transferrin reflect physiologic events not yet understood in the loading or unloading of iron by the proteins. Of possible relevance in this context, earlier studies from this laboratory have shown that absorbed iron is preferentially directed to the N-site of transferrin in the intact rabbit.[21]

Our present results are in qualitative accord with those reported earlier from this laboratory[12] and by Williams and Moreton.[13] In our earlier work antedating the introduction of Western blotting, crossed immunoelectrophoresis was used to identify and quantitate transferrin species. This procedure is more difficult to use for multiple samples than the presently employed Western blotting method and its quantitative reliability somewhat uncertain.[22] Furthermore, in the earlier study no precautions were taken to minimize artifacts caused by the improper storage of serum samples,[13] or by urea gel electrophoresis at pH 8.4, which may favor redistribution of iron to the N-terminal site of transferrin.[16] For these reasons, we believe our present findings are quantitatively more reliable than our earlier results in which the N:C ratio in six serum samples ranged from 3.5 to 28. In the study by Williams and Moreton, identification and quantitation of transferrin bands in urea gel preparations run at pH 8.4 and stained with Coomassie blue were made possible by precipitating most other serum proteins with the protein denaturant Rivanol. Using a different method for the estimation of apparent affinities for iron of the two sites of transferrin based on the rate of change of available sites with the change in iron loading rather than the thermodynamic approach we have used, these investigators found an average apparent affinity of the N-terminal site of circulating human transferrin to be 1.38 times greater than that of the C-terminal site, in reasonable agreement with our present result showing a mean N:C ratio of 1.60. The difference between the two values for the relative affinities of N- and C-sites may be due to variations in sample populations, to differences in methods of calculating the ratio, or to differences in methods for resolving and displaying the four forms of transferrin in serum.

Possible explanations for our unsatisfactory results with isoelectric focusing are that apotransferrin may be exposed to extraneous iron in commercial ampholytes that cannot be rendered free of iron and that initially saturated transferrin is partially depleted of iron by the low pH (5.0 to 5.4) at which it electrofocuses. For this reason, studies of transferrin polymorphism by isoelectric focusing, for which the high resolution of the technique is well suited, require that serum samples be overloaded with iron before analysis to insure that all the transferrin is kept in saturated form.[23] Further confounding the interpretation of isoelectric focusing patterns of transferrin is the microheterogeneity of the protein in the circulation resulting from variations in its sialic acid content. This microheterogeneity leads to an overlap of bands from species varying in the number of sialic acid residues with bands from species differing in iron content and distribution.[24] Such difficulties are not encountered in the urea gel electrophoresis technique, which is sensitive to the unfolding of iron-free domains of transferrin[25] rather than to small differences in charge. For these reasons we feel that analysis of the iron distribution in transferrin by urea gel electrophoresis is preferable to analysis by electrofocusing.

A random distribution of iron between the two binding sites of circulating transferrin is one in which each site is equally occupied, and the probability of this occupancy is given by the fractional saturation of transferrin with iron. It

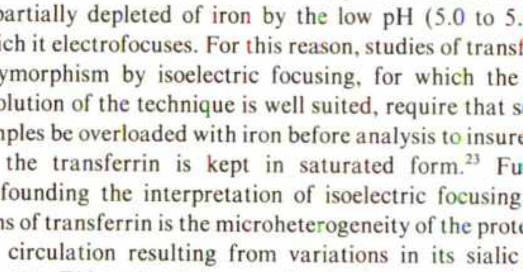

Fig 5. Theoretical plots of transferrin species bearing 0, 1, and 2 atoms of iron per molecule as a function of iron saturation. Calculations are based on the formulations of Chasteen and Williams,[16] assuming no interactions between the two sites of transferrin.

follows, therefore, that in a random distribution the concentrations of N-terminal and C-terminal monoferric transferrins must be equal. More importantly, inferences about random occupancy of the two binding sites of transferrin, founded on graphical representations of data in which only relative proportions of apotransferrin, diferric transferrin, and total monoferric transferrin are offered, as in the report by Huebers et al,[15] are conceptually flawed. From the formulations presented by Chasteen and Williams,[16] it may be shown that random distributions cannot be experimentally distinguished from nonrandom distributions when only total monoferric transferrin is considered, even if the relative occupancy of one site is as much as four times greater than the occupancy of its partner (Fig 5). This is because the relative proportion of total monoferric transferrin changes slowly with a change in the relative occupancies of N- and C-terminal sites, as shown in the series of curves in Fig 5. For iron distribution in circulating transferrin to be truly random, N- and C-terminal sites of the protein must be equally populated, and both monoferric forms must be present in equal concentration. That this is not the case is evident from the wide range of the N:C ratio, from 0.31 to 6.87 in our present study. Clearly, the distribution of iron in circulating transferrin is determined by other than random processes, but the nature of these processes remains unknown.

ACKNOWLEDGMENT

We are grateful to Dr David A. Baldwin and Mei Chen for their help in carrying out this work.

Purified Colony-Stimulating Factors Enhance the Survival of Human Neutrophils and Eosinophils In Vitro: A Rapid and Sensitive Microassay for Colony-Stimulating Factors

By C.G. Begley, A.F. Lopez, N.A. Nicola, D.J. Warren, M.A. Vadas, C.J. Sanderson, and D. Metcalf

The survival of purified human blood neutrophils and eosinophils was monitored using microwell cultures. Survival was enhanced in cultures containing human or murine colony-stimulating factors (CSFs). The survival of both cell types was enhanced by purified recombinant human granulocyte-macrophage CSF and partially purified preparations of the native molecule, CSFα. Neutrophil but not eosinophil survival was enhanced by murine granulocyte-CSF and its human analogue CSFβ. Eosinophil but not neutrophil survival was enhanced by murine eosinophil differentiation factor (eosinophil CSF). The mature cell survival provided an assay system for CSF that was 10^2 to 10^3 more sensitive than the standard assay of stimulation of colony formation in agar cultures and could be completed within 48 hours. These results demonstrated that CSF induced and enhanced survival of mature human neutrophils and eosinophils in vitro. Furthermore, the lineage specificity of purified murine CSFs was retained in their action on human cells.

© 1986 by Grune & Stratton, Inc.

THE AVAILABILITY of purified native and recombinant colony-stimulating factors (CSFs) has allowed the study of the effects of these molecules on populations of murine and human cells. In keeping with the action of CSFs to stimulate end cell functional activity[1,2] and the survival of progenitor cells,[3-7] evidence has been produced to suggest that CSF may be involved in prolonging survival of mature cells.[8,9]

Two human CSFs with granulocyte-macrophage activity have been identified from several sources of crude conditioned medium based on differences in hydrophobicity.[10-12] In the first eluting activity, CSFα stimulates functional activity of neutrophils and eosinophils whereas CSFβ stimulates neutrophils but not eosinophils.[1,2] Similarly, CSFα stimulates proliferation of neutrophil, macrophage, and eosinophil progenitor cells whereas CSFβ does not stimulate eosinophil colony formation.[6,10] The recombinant human granulocyte-macrophage CSF (rH GM-CSF)[13-15] is thus analogous to CSFα and possesses all the biologic activities previously described for the partially purified native molecule.[16]

An intriguing aspect regarding the action of CSFs is that the lineage-specific murine molecules (granulocyte CSF [G-CSF], eosinophil differentiation factor/eosinophil CSF [EDF/Eo-CSF]) are completely active and retain their lineage specificity on normal human cells.[2,12,17] Similarly, murine macrophage CSF (M-CSF) and human urinary M-CSF display antigenic and biochemical reactivities across species.[18,19] In contrast, neither the rH GM-CSF nor the murine GM-CSF display cross-species reactivities.[2,16,20]

These experiments were performed to examine whether the human-active CSFs could enhance the survival of mature neutrophils and eosinophils and whether this might be used as a rapid and sensitive assay for such CSFs.

MATERIALS AND METHODS

Preparation of purified neutrophils and eosinophils. Peripheral blood was obtained from healthy volunteers with their informed consent according to the guidelines laid down by the Ethics Committee of The Walter and Eliza Hall Institute. Neutrophils and eosinophils were purified on a discontinuous hypertonic metrizamide gradient as previously described.[21] The purity of these preparations was assessed by preparing cytocentrifuge smears and staining with May-Grünwald and 4% Giemsa. In all experiments the cell preparations were >98% pure for neutrophils and >95% pure for eosinophils. In some experiments contaminating red blood cells were removed from the eosinophils by hypotonic lysis in distilled water for 20 seconds. This procedure did not alter eosinophil survival in control experiments.

Microwell cultures of purified neutrophils and eosinophils. All cultures were performed using 60-well Lux 5260 HLA tissue culture plates (Miles Laboratories, Naperville, Ill). Each well contained 10 µL Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum (FCS) and 200 cells. Serial dilutions of 5 µL of CSF-containing preparations were added to the microwells prior to the addition of the target cells in the culture medium.

Cultures were incubated at 37 °C in a fully humidified atmosphere of 10% CO_2 in air.

Cultures were examined at intervals and direct cell counts performed on replicate wells using an inverted microscope at 200× magnification. With the optical conditions used (reduced lighting), viable cells had a sharp, clearly defined cell border and were highly refractile, whereas dead cells were dull, had no distinct edge, and often lacked any cytoplasm. Eosin was then added (5 µL) to each well, and cell counts were repeated ten minutes later using eosin exclusion as the measure of cell viability. Results of these two methods were compared.

In control experiments, cell counts were performed by two to four independent observers. Although there was some variation in the absolute cell numbers obtained (between 0% and 20%; mean, 6% for wells containing between 10 and 250 cells), the end points and the slopes of titration curves were the same.

Human marrow cell cultures. Marrow samples were obtained with the prior informed consent of patients undergoing cardiac surgery and according to a protocol approved by the Ethics Commit-

tee of The Walter and Eliza Hall Institute. Patients had no hematologic disease. Marrow cells were washed in Eisen's balanced salt solution and layered over Ficoll-Hypaque (1.077 g/mL) and centrifuged for 20 minutes at 1,000 g. Interface cells were washed and resuspended in DMEM containing 10% FCS. Cells were cultured in 35-mm Petri dishes using 1 mL of double strength DMEM and a final concentration of 20% FCS and 0.3% agar. A total of 2×10^4 cells were cultured per milliliter. Each culture dish contained 0.1 mL of CSF-containing preparations that were pretitrated to deliver a maximal stimulus and were without high-dose inhibition. Cultures were incubated in a fully humidified atmosphere of 10% CO_2 in air. Colony formation (clones of 40 or more cells) was scored at 35× magnifications using a dissection microscope after seven and 14 days of incubation.

CSF preparations. Human placental conditioned medium (HPCM) and the semipurified CSFα and CSFβ fractions were prepared as previously described[10,22] using phenyl-Sepharose chromatography of medium conditioned by the bladder carcinoma cell line U5637.[12]

The recombinant human GM-CSF (rH GM-CSF), provided by Drs E. Wang, G. Wong, and S. Clark, the Genetics Institute, Boston, was cloned from a cDNA library from the Mo human T leukemia cell line, expressed in monkey CV1 origin SV-40 (COS) cells, and purified as previously described.[13,16,23]

Purified murine G-CSF (6×10^8 U/mg) was prepared from mouse lung conditioned medium as previously described.[24] Murine EDF (Eo-CSF) was obtained from the medium conditioned by a murine T cell hybridoma[25] and purified as described.[26]

All CSF concentrations are expressed as the final concentration of CSF in the culture.

RESULTS

Neutrophil survival in vitro. Figure 1 shows the results of a typical experiment in which the survival of purified peripheral blood neutrophils was examined. For the first 15 hours of the culture period there was no difference between the survival of neutrophils in control cultures compared with cultures containing approximately 10 U/mL of rH GM-CSF, CSFα, or murine G-CSF. In Fig 1, the first time point at which dead cells were noted in control cultures was at 20 hours. The time at which death was first evident varied between 14 and 20 hours for neutrophils obtained from different individuals. On continued incubation, cell numbers continued to decline, and after approximately 35 hours, less than 10% of cells remained in control cultures of neutrophils from eight individuals examined.

Neutrophils in cultures containing CSF showed a consistent enhanced survival compared with cells in control cultures. In the example in Fig 1, this difference was most striking at the 28-hour time point, when the mean number of cells in control cultures was 10 compared with 100 cells in wells containing CSF. There was no apparent difference between rH GM-CSF, CSFα and murine G-CSF in terms of their ability to enhance neutrophil survival.

Eosinophil survival in vitro. The survival of purified human eosinophils in vitro was also enhanced when cells were cultured in the presence of CSF (Fig 2). At early time points there was no difference between control cultures and cultures containing CSF. Dead cells were first observed in control cultures at 26 hours (range, 18 to 28 hours for different individuals). Cell death was progressive in control cultures, and less than 10% of cells remained after approximately 40 hours for all individuals examined. The survival of eosinophils was enhanced in cultures containing CSF. The difference between control and CSF-containing cultures was most evident at the 40-hour time point (Fig 2), when the mean number of cells was 20 in control cultures compared with 108 in CSF-containing cultures. At equivalent concentrations there was no apparent difference between rH GM-CSF, CSFα, and murine EDF (Eo-CSF) in terms of their ability to enhance eosinophil survival in vitro.

Although these results did not necessarily document the maximal in vitro survival time in mature human neutrophils and eosinophils, they did demonstrate that survival in a standardized culture system was enhanced in CSF-stimulated cultures.

Eosinophils consistently showed a longer survival in vitro than neutrophils obtained from the same individual. The mean time taken for 50% of the cells to die in unstimulated cultures was 20 hours (mean of four experiments) for neutrophils and 30 hours for eosinophils.

Viable cell counts were performed on the same microwells in the presence and absence of eosin to test whether cell viability could be accurately assessed by direct visual examination. The results are shown in Fig 3. For neutrophils, cell viability was accurately assessed from the morphology of the

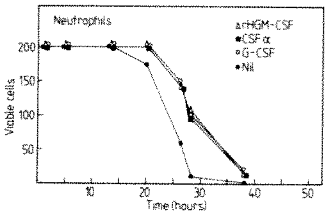

Fig 1. The survival of human blood neutrophils (>98% pure) in vitro in control cultures and cultures containing CSF. Cells were placed in microtiter trays (200 cells per well), and the number of viable cells was counted in four replicate wells at various time points thereafter. Cell survival was enhanced in cultures containing recombinant human GM-CSF (rH GM-CSF), semipurified human CSFα, and murine G-CSF. The concentration of CSF was approximately 10 U/mL as determined by normal human bone marrow colony formation.

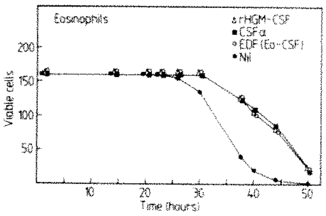

Fig 2. The survival of human blood eosinophils (>95% pure) in vitro in control cultures and cultures containing CSF. Cells were placed in microtiter trays (160 cells per well), and the number of viable cells was counted at varying times thereafter. Results shown are the means of four replicate wells. Cell survival was enhanced in cultures containing rH GM-CSF, semipurified human CSFα, and murine EDF (Eo-CSF). The concentration of CSF was approximately 10 U/mL as determined by normal human bone marrow colony formation.

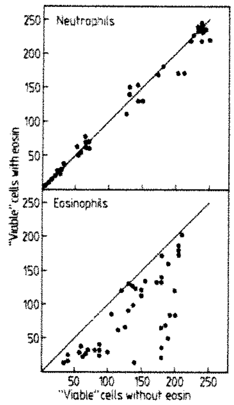

Fig 3. **Cell viability was examined either in cultures without eosin or in cultures with eosin added. Two hundred cells (either neutrophils or eosinophils) were placed in microtiter wells and examined at various time points thereafter. There was no difference in cell survival of neutrophils as assessed by simple inspection or the use of eosin (upper panel). Following the onset of cell death in cultures of eosinophils, eosin was required to accurately assess numbers of remaining viable cells (lower panel).**

cells in the absence of eosin (Fig 3, upper panel). This was because these cells disintegrated at or about the time they ceased to exclude eosin. In contrast, eosinophils maintained their apparent integrity for many hours after they had ceased being able to exclude eosin (Fig 3, lower panel).

Titration of survival-enhancement induced by rH GM-CSF. The activity of varying concentrations of purified rH GM-CSF in enhancing cell survival was examined, and a typical result is shown in Fig 4. Similar results were also obtained for equivalent concentrations of the partially purified native molecule CSFα, which shares all the biologic activities of the rH GM-CSF[16] (data not shown).

The upper panel (Fig 4) shows a titration of the rH GM-CSF at the 28-hour time point when purified neutrophils were used as the target cell population. This molecule was also effective in enhancing eosinophil survival (Fig 4, lower panel), and the responsiveness of the two cell types to CSF was very similar. These results were consistent with previous reports of this molecule being active in stimulating the functional activity of mature cell populations.[1,16] The initial concentration of rH GM-CSF shown in Fig 4 was 670 pg/mL. The lowest concentration of rH GM-CSF detected as enhancing survival was approximately 1.3 pg/mL.

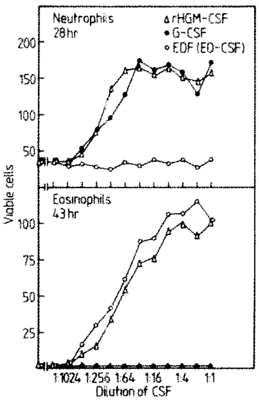

Fig 4. **Dose-response relationship for purified blood neutrophils (upper panel) and eosinophils (lower panel) when cultured with rH GM-CSF, murine G-CSF, and murine EDF (Eo-CSF). Two hundred cells were placed in microtiter trays, and the numbers of viable neutrophils were counted after 28 hours. Viable eosinophils were counted after 43 hours. Results are the means of replicate wells stimulated by twofold dilutions of each CSF preparation. The initial concentration of rH GM-CSF was 670 pg/mL.**

Enhancement of survival of human cells by murine G-CSF and EDF (Eo-CSF). Murine G-CSF and murine EDF (Eo-CSF) are able to stimulate the proliferation of human progenitor cells and functional activity of human neutrophils or eosinophils in a lineage-restricted manner.[2,12,17] The action of these purified murine molecules was examined as shown in Fig 4.

Neutrophil survival was enhanced when cells were cultured in the presence of murine G-CSF. Similar results were obtained when cells were cultured with human CSFβ, the human analogue of murine G-CSF[12] (data not shown). Murine EDF (Eo-CSF) was inactive (Fig 4, upper panel), suggesting that enhanced survival was a specific, CSF-mediated response.

Eosinophil survival was enhanced by murine EDF (Eo-CSF) whereas murine G-CSF and human CSFβ were inactive upon these cells (Fig 4, lower panel). These results confirmed and extended previous descriptions of the activities of these purified murine molecules upon specific populations of human cells and argue strongly against a purely nonspecific survival-enhancing action of the CSFs on these cells.

Morphologic changes induced by CSF. At higher concentrations of CSF both neutrophils and eosinophils underwent a striking morphologic change similar to that previously described for neutrophils, for example, with *N*-formylmethionine-leucine-phenylalanine or influenza virus.[27] Cells ceased to be spherical and assumed irregular shapes, becoming elongated, "tear drop," and convoluted in appearance. These morphologic changes were maximal within one-quarter to one-half hour and reversed over several hours. The viability of these cells subsequently was significantly compromised compared with cells held at lower concentrations of CSF where no such change was observed but where survival was prolonged. The rH GM-CSF and CSFα induced this morphologic change in both neutrophils and eosinophils. Murine G-CSF and human CSFβ induced similar acute morphologic changes in neutrophils but not eosinophils, and the murine EDF (Eo-CSF) induced changes in eosinophils but not neutrophils, indicating that this was a specific result of stimulation by CSF. The concentration of rH GM-CSF above which this morphologic change was observed in >50% of the cells in one hour was approximately 50 pg/mL. Similarly, higher concentrations were required for the other CSFs than the concentrations at which survival was enhanced. Less than 5% of the cells in unstimulated cultures demonstrated this change.

Higher sensitivity of survival assay compared with colony assay. Figure 5 shows the stimulation by purified rH GM-CSF of colony formation by normal human bone marrow cells. This factor preferentially stimulated the day 14

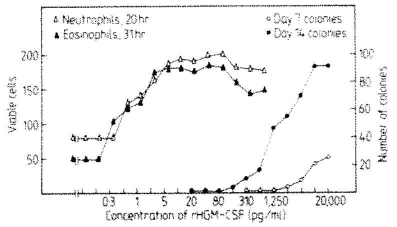

Fig 5. Relative sensitivity of CSF assays during colony formation or survival of mature cells stimulated by rH GM-CSF. A quantity of 2 × 10^4 marrow cells were cultured per milliliter, and colonies (>40 cells) were scored on day 7 and day 14 of culture. The initial concentration of rH GM-CSF was 18,200 pg/mL. The ability of rH GM-CSF to enhance survival of mature neutrophils and eosinophils is also shown. Two hundred cells were cultured in 15-μL volumes and viable cells counted at 20 hours (for neutrophils) and 31 hours (for eosinophils). The initial concentration of rH GM-CSF was 670 pg/mL. All concentrations are expressed as the final rH GM-CSF concentration in the culture.

subset of human colony-forming cells that includes neutrophil, macrophage, and eosinophil colonies.[16] The starting concentration was 18.2 ng/mL of rH GM-CSF. A titration of the rH GM-CSF on neutrophil and eosinophil survival is shown for comparison. The starting concentration was 0.67 ng/mL in the microwell assay. The lowest concentration of rH GM-CSF detected in the colony-forming assay was approximately 280 pg/mL compared with approximately 0.7 pg/mL in the microassay.

The sensitivity of the microassay was greater than that of the colony assay by 5 × 10^2-fold. In other experiments, the greater sensitivity of the microassay ranged between 10^2- to 10^3-fold for the rH GM-CSF. This heightened degree of sensitivity was also seen with CSFα, CSFβ, and murine G-CSF (data not shown).

DISCUSSION

This study has demonstrated that purified CSFs induce enhanced survival of purified populations of mature human neutrophils and eosinophils in vitro. Previous experiments have shown that survival of progenitor cells is dependent upon CSF,[3-7] and these observations have now been extended by the demonstration of a similar type of lineage-specific action for CSF upon mature cells. Furthermore, the lineage specificity of murine G-CSF and murine EDF (Eo-CSF) for murine cells[24,25,28] is retained in their action on human cells. The rH GM-CSF, on the other hand, was shown to stimulate enhanced survival of both neutrophils and eosinophils. The dual lineage activity of this molecule has been previously documented for progenitor and mature cell populations,[16] thus making it analogous to the murine GM-CSF.[29] It is intriguing, however, that despite biologic and sequence homologies neither molecule appears to show a cross-species reactivity.[16,20]

Several microassay systems have been described that are dependent upon proliferation of target cell populations to detect CSF.[20,30-34] These systems are of value because of the small volumes of CSF required and because of the heightened sensitivity of CSF that such murine assays display.[30-33] There is no evidence, however, that proliferation-dependent human microassays are more sensitive to CSF than traditional agar assays.[20,34] The assay described here is thus unique in displaying an increased sensitivity to CSF, between 10^2- and 10^3-fold the sensitivity of agar assays. Furthermore, this assay provides a rapid result but retains lineage specificity for the different CSFs.

The heightened sensitivity to CSF of this microassay compared with other human microassays or agar assays is likely to be the consequence of differences in both the target cell population used and the end point of the assay. Several studies have demonstrated that a heightened sensitivity to CSF is associated with differentiation within progenitor cell compartments since promyelocytes-myelocytes (cluster-forming cells) are more sensitive to CSF than blast cells (colony-forming cells).[35-37] Furthermore, lower concentrations of CSF are required for survival of progenitor cells than the levels required for proliferation.[33] This study has taken advantage of both these observations by using terminally differentiated (and therefore probably the most CSF-responsive) cells and examining cell survival rather than a functional end point.

For progenitor cells, the particular elicited response to CSF (ie, survival *v* proliferation *v* differentiation) is dependent upon the concentration of CSF.[33,38-40] This may also be true for mature cells, since the level of CSF required for the morphologic change of polarity to occur within cells was approximately 10^2-fold the concentration of CSF required for cell survival. This suggests a differential response to varying CSF concentrations by mature neutrophils and eosinophils.

The technique described here provides a rapid, sensitive, specific assay for CSF, and as such, may be useful in examining supernatants obtained from candidate CSF-cDNA clones. The demonstration that mature cell survival is dependent upon CSF has potentially important clinical applications, particularly in areas such as granulocyte transfusion, where viability and function of transfused cells may well be enhanced by the addition of CSF.

Release of Galactosyltransferase From Human Platelets and a Subset of Monocytes in Culture

By K.E. Hopper, Anita D. Semler, G.V. Chapman, and R.A. Davey

We show that human monocytes and platelets release considerable amounts of galactosyltransferase (GT) in serum-free culture as measured by the amount of incorporation of ^{3}H-galactose into ovalbumin. Enzyme production was the greatest among medium-sized mononuclear cells separated by counter-current elutriation. The cells were adherent and positive for the monocyte-specific monoclonal antibody FMC-32. The activity in the monocyte fractions was not due to platelet contamination as shown from experiments in which platelets or platelet antigens were eliminated. Cell viability decreased by less than 3% during the overnight culture, and results from cell disruption experiments showed that the enzyme was not released from dead or dying cells. Cycloheximide inhibited release during 20 hours culture. Approximately 50% of the enzyme in the cell culture supernatant was pelletable at 105,000 g. Platelets released the enzyme more rapidly than did monocytes and were readily stimulated by thrombin to release more GT. Thrombin also increased monocyte GT activity after overnight incubation, but other stimulants, zymosan and lipopolysaccharide (LPS), decreased release. We conclude that GT is released into culture supernatants by platelets and by a subset of peripheral blood monocytes. These sources may account for a significant proportion of the serum enzyme and may be important in modification of extracellular carbohydrates during inflammation and coagulation.

© 1986 by Grune & Stratton, Inc.

MANY CELLULAR interactions and functions depend on extracellular carbohydrates, either as cell surface components or as parts of secreted glycoproteins.[1] Enzymatic or chemical modification of the carbohydrate leads to changes in these reactions such as lymphocyte blastogenesis induced by periodate[2] or neuraminidase and galactose oxidase[3] or clearance of desialated glycoproteins by macrophages or hepatocytes.[4] Ectogalactosyltransferases are normal components of serum[5] and are elevated in patients with cancer,[6] liver damage, and acute inflammation.[7] They are secreted by tumor cells[8] and are postulated to be markers for the presence of cancer.[5,9] Hepatocytes[10] and macrophages[11-13] have also been suggested as normal sources of extracellular galactosyltransferase (GT).

We have shown in mice that peritoneal macrophages induced in the early phases of inflammation after a single injection of thioglycollate broth or salmonella release large amounts of GT in culture.[13] Inflammation induced by secondary infection or immune responses in the peritoneal cavity did not lead to release of enzyme. Our studies suggested that the secreting cells in mice were platelets and newly recruited monocytes. We show here that platelets and a subpopulation of small monocytes are responsible for most of the enzyme released by normal human peripheral blood cells in culture.

MATERIALS AND METHODS

Preparation of cells. Citrated human peripheral blood was diluted in the ratio of 1:2 with Hanks' balanced salt solution without Ca^{++} or Mg^{++} (HBSS, GIBCO, Grand Island, NY) in 50 mL polypropylene centrifuge tubes (Crown Corning, Chicago). This was underlayed with Lympho-paque (Nyegaard & Co, Oslo) in a ratio of one part to three parts diluted blood and centrifuged for 40 minutes at 300 g and 18 °C. The buffy interface was recovered, diluted fivefold with HBSS without Ca^{++} or Mg^{++}, centrifuged, and the cell pellet resuspended and washed twice. Neutophils of $\geq$99% purity were prepared as described previously.[14] Citrated blood was centrifuged at 200 g for ten minutes. The platelet-rich plasma was removed and spun at 800 g for 20 minutes, the plasma discarded, and the pellet dispersed and washed (three times) with acid-citrate-dextrose. The platelets were finally washed in HBSS without Ca^{++} or Mg^{++}.

Cell counting. Cell viability and number were estimated by Trypan blue exclusion. Slide preparations (Cytospin, Shandon Southern Products Ltd, Runcon, England) were stained with May-Grünwald Giemsa or for nonspecific esterase.[15]

Separation of cells by counter-current elutriation (CCE). Peripheral blood mononuclear cells were separated by CCE using a Beckman 6.0 rotor with a standard chamber in a J-6B centrifuge (Beckman Instruments, Inc, Palo Alto, Calif) and fitted with a Masterflex peristaltic pump and silicone tubing (Silastic, Dow Corning Corp, Midland, Mich). The rotor chamber was treated with silicone solution (Desicote, Beckman) before rotor assembly, and then 70% ethanol (400 mL), saline (1,000 mL), and elutriation medium (200 mL) were pumped through the apparatus with the rotor running at 2,200 rpm. The elutriation medium consisted of HBSS without Ca^{++} or Mg^{++} containing 0.4% bovine serum albumin (Cohn Fraction V, CSL, Parkville, Australia) and 0.38% sodium citrate. The pump was calibrated immediately before introduction of the sample and pump speeds adjusted to give appropriate corrected flow rates for each fraction. The cell sample (50 to 200 × 10^6 mononuclear cells in 10 mL HBSS without Ca^{++} or Mg^{++}) was applied via a 30-mL loading chamber at a pump speed of 8.0 mL/min. Samples of 100 mL were collected into cold polypropylene tubes from the start of sample application and each filled tube stored on ice. The pump speed was increased stepwise from 8.0 to 22.0 mL/min at a constant rotor speed of 2,200 rpm and then the rotor stopped to elute the remaining cells. After the run, the assembly was washed through with 5% detergent (200 mL, Solution 555, Beckman) followed by 2 L water and left to dry.

The fractions were centrifuged for ten minutes at 300 g and 4 °C, washed twice with cold HBSS without Ca^{++} or Mg^{++}, and then made up to 2 mL with Dulbecco's modified Eagle's medium (DMEM) (GIBCO) containing 100 µg/mL streptomycin and 100

U/mL penicillin. Total cell recovery was 70% to 90% of the starting population.

Cell separation in EDTA-containing media. In experiments designed to totally eliminate platelets from the monocytes, the cell preparation (after the Lympho-paque separation) and the elutriation were carried out at 4 °C in media containing 0.5 mmol/L EDTA rather than citrate. The pump speeds were adjusted to give fractions of similar composition to those in media containing citrate. All other experiments were carried out using cells prepared in citrated medium.

Adherence of cells. The cells (3 × 10^5) in 100 μL DMEM containing 10% heat-inactivated human AB serum (56 °C for 30 minutes) were incubated for 90 minutes at 37 °C in 96-well flat-bottomed Linbro microtiter plates (Linbro Scientific Co, Inc, New Haven, Conn). The wells were gently washed with warm DMEM and the nonadherent cells aspirated. The washings from three aspirations were pooled, centrifuged, and 100 μL of DMEM was added to the nonadherent cells and adherent cells.

Cell culture. Mononuclear cells and neutrophils were incubated in Linbro flat-bottomed 96-well plates at 3 × 10^5 cells per well in 100 μL DMEM without serum supplement. Platelets were cultured at 10^7 cells per well in DMEM unless otherwise specified. In some experiments cultures contained human thrombin (Sigma Chemical Co, St Louis), lipopolysaccharide (type W from *Escherichia coli*, Difco Laboratories, Detroit Mich), or zymosan (Zymosan A from *Saccharomyces cerevisiae* yeast, Sigma) prepared in DMEM.

GT assay. GT was assayed as described previously[13,16] using 2.4 μmol uridine diphosphate-[^{3}H]-galactose (The Radiochemical Centre, Amersham, England) as the substrate and 1.8 mg ovalbumin as the acceptor in a total volume of 0.15 mL. Samples of normal serum assayed under the same conditions as culture supernatants gave values of GT activity of 20,000 to 40,000 cpm per 6 μL.

Disruption of cells. After specified incubation periods, (1) Triton X-100 (Sigma, St Louis) (0.5% final concentration) was added to the cells and incubated for 30 minutes at 37 °C, or (2) the cells in 1.5-mL polypropylene centrifuge tubes (Mallinckrodt Ltd, Clayton, Australia) were frozen in liquid nitrogen and thawed at room temperature (3 times) before assay. The cells were totally disrupted after Triton treatment and killed but partially intact after freezing and thawing.

Use of monoclonal antibodies. The monocyte-specific monoclonal antibody FMC-32[17] and platelet-specific monoclonal HuPl-M1[18] were obtained from Australian Monoclonal Development (Artarmon, Australia). The antiplatelet monoclonal PLT-1 was purchased from Coulter Electronics, Inc, (Hialeah, Fla). The cells (1 to 3 × 10^6) were prepared in phosphate-buffered saline containing 1% heat-inactivated human AB serum (PBS + serum). The pelleted cells were incubated with 50 μL of a 1:200 dilution of the antibodies for 30 minutes on ice, washed three times with 1 mL PBS + serum and incubated with 50 μL of a 1:50 dilution of fluorescein isothiocyanate (FITC) conjugated, F(ab′)$_2$ fraction of sheep antimouse Ig (Silenus Laboratories Pty, Ltd, Dandenong, Australia). The cells were washed three times in cold PBS + serum. Control cultures contained either no first antibody or normal mouse immunoglobulins (Coulter Electronics). Wet slide preparations of the cells were viewed at 400× magnification.

Platelets were also identified in separate cytospin slide preparations after staining with monoclonal antibody to factor VIII–related antigen and peroxidase-conjugated goat antimouse Ig (Dakoplatts, Glostrup, Denmark).

Flow cytometry. Analysis and sorting were performed on a Coulter EPICS V flow cytometer (Coulter Electronics) equipped with a Spectra physics Argonion laser (Mountainview, Calif) operated at 488 nm and a power of 400 mW. Two-parameter histograms of forward-angle light scatter (FALS) *v* log-integrated green fluorescence (LIGFL) were collected gated on FALS to exclude cell debris and clumps. Routinely, data on 10^4 cells were collected and analyzed.

RESULTS

Identification of cells secreting GT. Peripheral blood mononuclear cells were separated by CCE, and pooled fractions were cultured overnight in serum-free conditions. As shown in Fig 1, high activity was detected in the supernatant of cells in fraction 1 and among the medium-sized cells in fractions 4, 5, and 6. Cell viability remained greater than 95% after incubation for all fractions except fraction 1, which was 91%.

Fractions 4, 5, and 6 consisted of a mixture of large lymphocytes and small monocytes, and the enzyme release increased with cell number in culture (Fig 2A). Low levels of enzyme were produced by small lymphocytes in fractions 2 and 3 and decreasing amounts by cells in fractions 7 and 8, which were enriched for large monocytes. Fraction 8 also contained some polymorphonuclear leukocytes. Neutrophils prepared by density centrifugation over metrizamide did not release large amounts of enzyme (Fig 2A).

The predominant cells in fraction 1 were platelets. Similar amounts of enzyme were released from this fraction as from the same number of platelets prepared from platelet-rich plasma and purified by repeated low-speed centrifugation (Fig 2b).

Identification and separation of monocytes. To determine whether large lymphocytes or small monocytes in the middle fractions of the elutriation were responsible for

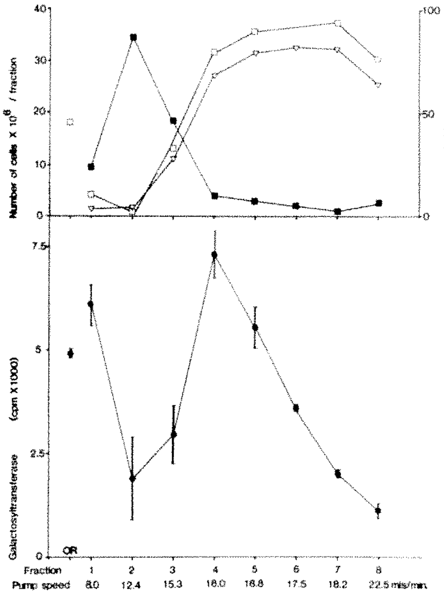

Fig 1. Separation of peripheral blood mononuclear cells by elutriation and release of GT in culture. Figure 1A shows the number of viable nucleated cells per fraction (-■-) and the percentage of monocytes in each fraction identified by morphology (-□-) or esterase staining (-▽-). Figure 1B shows the amount of GT released in culture by 3 × 105 cells from each fraction. Data points represent the mean ± SD of values from triplicate cultures. OR is the unseparated population.

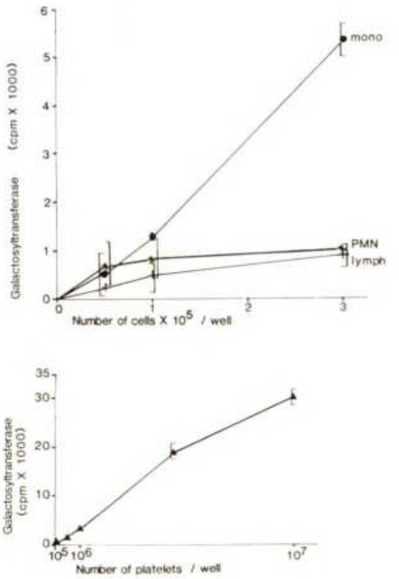

Fig 2. Release of GT from enriched cell populations. Figure 2A shows the GT released from monocytes prepared from elutriation fractions 5 and 6 (-●-), lymphocytes from fraction 2 and 3 (-+-), and neutrophils from metrizamide separation of dextran-sedimented blood cells (-#-). Figure 2B shows the GT released from platelets isolated from platelet-rich plasma.

releasing GT, the cells were separated further by flow cytometry or adherence. Monocytes were separated from other cells in fractions 5 and 6 by flow cytometry using the monocyte-specific monoclonal antibody FMC-32. The separated FMC-32–positive cells, comprising 80.0% of the cells in the fraction, were enriched for monocytes (>98% based on morphology). Most enzyme was released from the FMC-32–positive cells during overnight culture, whereas the unseparated cells released low amounts of GT (Fig 3).

Cells from all fractions were allowed to adhere to plastic for 90 minutes in the presence of heat-inactivated AB serum. The nonadherent cells were removed and the adherent, nonadherent, and unseparated populations washed and cultured for 16 hours to determine the release of GT. Adherence was effective in separating those cells releasing GT from inactive cells in fractions 5 to 8 (data for fraction 5: adherent cells, 2,603 ± 303 cpm; nonadherent cells, 283 ± 207 cpm; and unseparated cells, 4,166 ± 62 cpm). The amount of enzyme recovered from both adherent and nonadherent cells did not total that released by the unseparated population, suggesting that the adherence step affected the release of enzyme or that some active cells were lost.

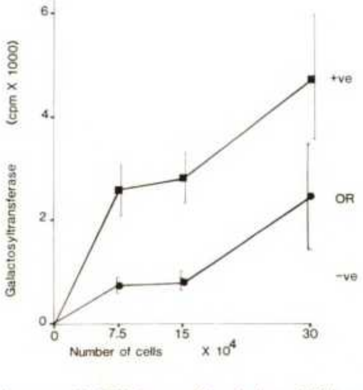

Fig 3. Release of GT by cells during 18-hour culture of FMC-32–positive sorted cells (-■-) and the unseparated populations (-●-).

The adherence treatment was found to be generally less effective in isolating monocytes from fractions 4 and 5 compared with fractions 6, 7, and 8. Loss of monocytes by binding to vessel walls was also a constant problem in fractions 7 and 8 but not in fractions 5 and 6, suggesting that monocyte adherence is greater among cells eluting later in the separation.

Identification and separation of platelets. Decreasing numbers of platelets were observed and clearly distinguished from other cells in fractions 1, 2, and 3, and few were observed in fractions 4 to 8. Using the platelet-specific monoclonal antibodies HuP1-M1 and PLT-1, no free, positive platelets were detected in fractions 4 to 8 by flow cytometric or microscopic examination. The majority of monocytes, however, were weakly positive for this antigen. Cytospin preparations of cells stained with factor VIII–related antigen did show some intact platelets bound to about 10% of the monocytes. These results suggested that the flow cytometric analyses had detected platelet antigens or fragments rather than intact platelets on the monocyte surface.

To determine whether the GT from monocyte fractions had come from monocytes or platelets, the cell preparation and elutriation conditions were changed (using EDTA and low temperature instead of citrate at 18 °C) to give a more stringent prevention of monocyte-platelet adhesion (see Materials and Methods). The monocyte-enriched fractions were totally free of platelet antigens as determined by flow cytometry using PLT-1 (Fig 4) and HuP1-M1 (data not shown) and microscopy using factor VIII–related antigen. GT production in culture was again greatest from monocyte-enriched fractions, and similar total amounts of GT were released from cells prepared in citrate or EDTA. However, using EDTA, there was no difference in GT release per monocyte by cells across the elutriation profile. When 0.5 mmol/L EDTA was included in the culture of cells prepared

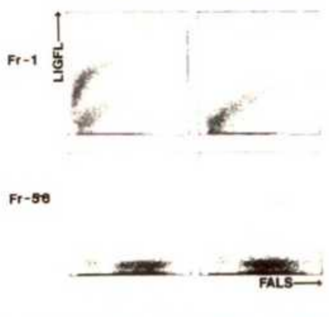

Fig 4. Two-parameter flow cytometry histograms of cells in fraction 1 and pooled fraction 5 to 8 obtained by elutriation at low temperature in EDTA-containing media. Flow cytometry patterns show light scatter on the abscissa and log fluorescent staining on the ordinate. The cells were stained indirectly with PLT-1 or second antibody alone.

in citrated elutriation medium, there was an increase in the release of GT (3,125 ± 234 cpm with EDTA and 2,046 ± 761 without EDTA).

Effect of cell disruption on release of GT. In agreement with previous experiments using mouse peritoneal macrophages, a significant proportion of the released enzyme from human monocytes was pelletable at 105,000 g (3,083 ± 636 cpm in the supernatant before and 2,087 ± 280 cpm after centrifugation). Enzyme activity in culture supernatants from platelets was also decreased by 25% by centrifugation. Some of the enzyme may therefore be released in membrane fragments from dying cells. Maintenance of high cell viability in culture would argue against this. However, to determine the potential of the cells to release preformed enzyme, cells in fractions 5 and 6 were cultured for four or 20 hours and then treated with Triton X-100 or were frozen and thawed (three cycles) (Fig 5). The lysates were centrifuged at 200g and the GT in the supernatants assayed. Consistently more enzyme was released after treatment with Triton, and there was little increase in GT with time of culture. The relatively low amount of enzyme available after Triton treatment suggested, however, that the enzyme released in culture was not coming from dead cells.

Freezing and thawing did not release large amounts of enzyme. There was no difference in the amount of released GT if the frozen-thawed cells were centrifuged at 200 g, and very little enzyme was detected if the cells were centrifuged before lysis.

Cycloheximide at 10^{-5} mol/L included in the cell culture partially inhibited the release of GT overnight (1,410 ± 259 cpm with, 2,916 ± 52 without inhibitor), but not during the four-hour culture (1,447 ± 323 with, 725 ± 65 without inhibitor). Lower concentrations of inhibitor had no effect at either time.

Effect of cell stimulation. Platelets prepared from fraction 1 and mononuclear cells from pooled fractions 5 and 6 were incubated with thrombin for two hours or 16 hours. As shown in Fig 6, thrombin caused a marked increase in GT release from platelets but not monocytes during the two-hour incubation. When monocytes were incubated for 16 hours with thrombin, there was a significant increase in release. In other experiments the effect of thrombin on platelets was detected within minutes of addition (data not shown), and results for 4, 6, or 16 hours were similar, indicating that for a given amount of thrombin the platelets were probably maximally stimulated very early during the incubation. In control experiments, thrombin was added to preformed supernatants from cultures of monocytes or platelets to determine the effect of the protease on GT. There was a 30% reduction in the activity of the monocyte supernatant and a 10% reduction in the activity of the supernatant from platelets cultured more than 16 hours.

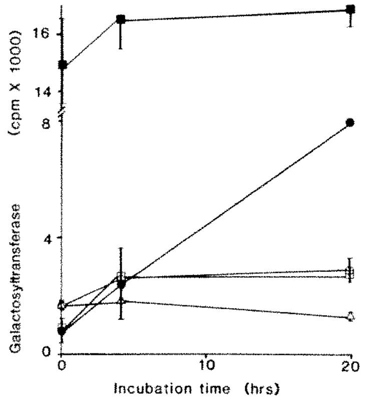

Fig 5. Effect of cell disruption on release of GT. Cells in elutriation fractions 5 and 6 were cultured and treated with Triton X-100 (-■-) or frozen and thawed (open symbols) and the amounts of GT released compared with that from untreated cells in culture (-●-). Three protocols of freezing and thawing are shown: (-○-), the cells were cultured, frozen, and thawed and the whole lysate assayed; (-□-), the lysate was centrifuged at 800 g and the supernatant assayed; (-△-), after incubation the cells were washed twice and then lysed.

Opsonized zymosan and lipopolysaccharide (LPS) are potent monocyte stimulants, and in other experiments treatment of monocytes with LPS increased tumoricidal and procoagulant activities, whereas opsonized zymosan stimulated the generation of chemiluminescence (Andrews and Hopper, data not shown). As shown in Fig 7, however, LPS caused a reduction in GT release from monocytes and, to a lesser extent, from platelets cultured more than 18 hours. Similar results were obtained using opsonized zymosan or both agents incubated for four hours.

DISCUSSION

The liver is believed to be the major source of GT in blood.[7] We conclude from this study that normal human platelets and a subset of small monocytes from peripheral blood release considerable amounts of GT into the supernatant of serum-free cultures. If similar GT production occurs in vivo, this would account for a small but significant proportion (probably about 5% based on cell numbers) of the free enzyme in normal blood. These results confirm, and extend

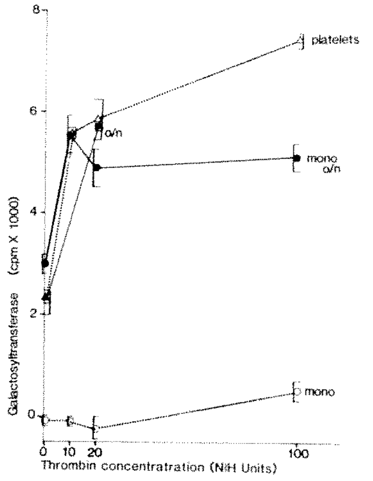

Fig 6. Effect of the addition of thrombin to platelets (triangles) (fraction 1, 10^7) and monocytes (circles) (fraction 5 and 6, on release of GT during culture for two hours (△▲) or 16 hours (○●).

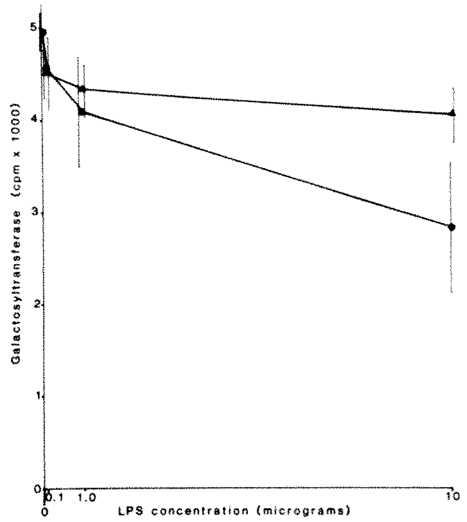

Fig 7. Effect of LPS on release of GT from platelets (▲) and monocytes (●) during an 18-hour incubation.

to humans, our previous studies using mice in which we showed that subpopulations of monocytes/macrophages that had been recently recruited to an acute inflammatory reaction in the peripheral cavity produced large amounts of this enzyme.[13] Conditions for the release of GT appear to be the same in both species. We postulated in the case of the mouse that the secreting cells may constitute a subpopulation of monocytes or be in a particular activation state that is induced in acute inflammation. This may lead to local concentration of the enzymes.

Monocyte subpopulations have been separated in several[19,20] but not all previous studies[21,22] using CCE. We confirm that CCE can separate monocyte subsets that have different adherence and ability to release GT. It should be noted that, using low temperature and EDTA in the elutriation, all monocytes were equally capable of GT release and therefore differ from the cells prepared in citrate. This may be due to an effect of these conditions on enzyme release or on different resolution of cell subsets.

Loss of monocytes by adherence to vessels and tubes is a major problem in these separations, and from our observations, this is more serious for monocytes of high sedimentation velocity. In an attempt to overcome these problems, the cells were prepared and collected as quickly as possible using new polypropylene tubes with citrate or EDTA in the Ca^{++}- and Mg^{++}-free elutriation media and after separation keeping the cells at 0 to 4 °C. Citrate was the preferred chelator in the elutriation media because of the tendency of EDTA to cause vacuolation at higher concentrations.[23]

Monocytes prepared conventionally over discontinuous gradients are known to be contaminated by platelets, either as aggregates or bound to monocytes.[24] We have found, in addition, that contamination by platelet fragments is more extensive than by intact platelets and that almost all monocytes, but not other cells, have platelet antigens on their surface. Platelets could therefore be the source of the released GT in the fractions separated by CCE. Several results, however, would argue against this. (1) In confirmatory experiments platelet aggregation and contamination of fractions 4 to 8 were essentially eliminated by strict Ca^{++}- and Mg^{++}-free conditions and low temperature, whereas GT production was not diminished in these monocyte-enriched fractions. (2) Enzyme was released more rapidly from platelets, and these cells were much more sensitive to the presence of thrombin than monocytes during the two-hour incubation. (3) Serum GT exists as a family of enzymes that are separable by isoelectric focusing.[9] We have found that cell culture supernatant GT shows qualitatively similar focusing patterns to serum, but with major differences in amounts of some isoenzymes (Davey and Hopper, manuscript in preparation). The focusing patterns of GT released from platelets differed from that released by monocytes.

Since GTs are membrane-bound intracellular enzymes, it is possible that the released enzyme may come from dead cells that had disintegrated. This does not appear to be the case because cell viability remained high throughout the incubation (above 95%) and complete solubilization of the cells with Triton X-100 only doubled the amount of available enzyme rather than an expected severalfold increase if all cells were equally capable of producing GT. There was, however, a net loss of cellular enzyme during incubation.

Freezing and thawing did not release more enzyme than that obtained from the viable cell culture. There was a decrease in the supernatant enzyme, however, if the cells were cultured and then lysed. This result is probably due to incomplete disruption of the cell membranes and lack of solubilization of membrane-bound enzyme during the freezing and thawing compared with the lysis with detergent. In comparison, mouse cells did release more GT after freezing and thawing and the results suggested the presence of a pool of free enzyme.[13]

The rapid release of GT from platelets and their sensitivity to the effect of thrombin suggest that the enzyme arises by degranulation of these cells. The mechanism of release of GT from monocytes is not understood. Some of the GT released from platelets and monocytes was pelletable at 105,000 g and therefore may be liberated within vesicles during membrane turnover. Adherence, phagocytosis of opsonized zymosan particles, and incubation with LPS reduced the amount of enzyme released, and these processes would be expected to alter membrane stability and turnover. Increased membrane fluidity may be a property of the monocyte subset responsible for GT release. Under the same conditions as used here, monocytes showed procoagulant activity when stimulated by LPS and chemiluminescence by opsonized zymosan (Andrews and Hopper, unpublished observations). Typical techniques for the stimulation of monocytes, therefore, did not promote release of GT. Thrombin did, however, cause an increased release of GT from monocytes during overnight culture. Thrombin is also known to bind to monocytes[25] and act as a chemoattractant.[26] An interesting hypothesis for the mechanism of release of GT may be the conversion of membrane-bound enzyme to an active hydrophilic form by limited proteolysis.[27] Such a mechanism would also be in agreement with our previous data on the effects of thrombin and trypsin on mouse cells and the lack of effect of other metabolic inhibitors. Cycloheximide was only partially effective in inhibiting release after 20 hours and was not inhibitory after four hours, suggesting that the enzyme may not be immediately available for release after synthesis.

Platelets and monocytes are involved in many related aspects of inflammatory and coagulation reactions. Since in this paper we show that significant amounts of GT are released from both these cell types, it may indicate that GT is an additional mechanism for modification of extracellular carbohydrate.

ACKNOWLEDGMENT

We are grateful to Drs C.L. Geczy and D.S. Nelson for helpful discussions throughout the study, Amanda O'Toole for preparing immunoperoxidase-stained slides, and Jocelyn Sharp for typing.

Analysis of Human Platelet Glycoproteins IIb-IIIa and Glanzmann's Thrombasthenia in Whole Blood by Flow Cytometry

By Lisa K. Jennings, Richard A. Ashmun, Winfred C. Wang, and Michael E. Dockter

Antibodies that bind to human platelet membrane glycoproteins IIb and IIIa were used to develop methods for analyzing platelet membrane components by flow cytometry. Platelets were tentatively identified by their low-intensity light scatter profiles in whole blood or platelet-rich plasma preparations. Identification of this cell population as platelets was verified by using platelet-specific antibodies and fluorescein-conjugated antiimmunoglobulin. Two-parameter analysis of light scatter versus fluorescence intensity identified >98% of the cells in the "platelet" light scatter profile as platelets due to their acquired fluorescence. Both platelet-rich plasma and whole blood were used to study platelet membrane glycoproteins IIb and IIIa on a single cell basis in an unwashed system. Prostacycline was included in these preparations as a precautionary step to inhibit platelet aggregation during analysis. Flow cytometry is a successful technique for rapid detection of platelet membrane defects such as Glanzmann's thrombasthenia. Platelets from Glanzmann's thrombasthenic individuals were readily distinguished from platelets with normal levels of glycoprotein IIb and IIIa and from platelets with glycoprotein levels characteristic of hetrozygote carriers of this disorder. This technique provides a sensitive tool for investigating platelet functional defects due to altered expression or deficiency of platelet surface proteins.

© 1986 by Grune & Stratton, Inc.

FLOW cytometry is a technique that is being increasingly used to analyze individual components in a homogeneous or heterogeneous population of cells. Analysis by flow cytometry has been used successfully to quantitate cellular DNA and ploidy frequency distributions of cells, particularly those residing in the bone marrow, and has been increasingly used for analysis of ligand-receptor interactions (for review, see references 1 and 2). Flow cytometry may provide one of the best overall methods for analysis of receptor proteins as this technique permits rapid and sensitive analysis of cell surface proteins on a single cell basis.

We have developed a method for analyzing platelet surface components in platelet-rich plasma and whole blood using flow cytometry. Platelet membrane glycoproteins IIb and IIIa were detected on the platelet surface by using as probes monoclonal or heterologous antibodies specific for these glycoproteins. The level of glycoproteins IIb and IIIa on platelets from normal donors was compared to that of platelets obtained from Glanzmann's thrombasthenic individuals. Platelets from individuals with Glanzmann's thrombasthenia and heterozygote carriers for this disorder were easily distinguished by their relative fluorescence intensity from platelets of normal donors. During our studies, we also observed that all cells within the platelet population displayed decreased amounts of glycoproteins IIb and IIIa (characteristic of this inherited platelet disorder), thus confirming that this is a homogeneous defect. Platelet analysis by flow cytometry provides an alternative rapid diagnostic procedure for Glanzmann's thrombasthenia as well as for the detection of other functional defects caused by an altered expression of platelet surface components.

MATERIALS AND METHODS

Chemicals and Materials

Acrylamide, n,n'-methylene bis-acrylamide, ammonium persulfate, bromophenol blue, sodium dodecyl sulfate (SDS), Coomassie brilliant blue, and molecular weight standards were obtained from Bio-Rad (Richmond, Calif). Lactoperoxidase was a generous gift from Dr M. Morrison (St. Jude Children's Research Hospital, Memphis, Tenn). Na^{125}I was purchased from New England Nuclear (Boston, Mass). All other chemicals were purchased from Sigma Chemical Co (St. Louis, Mo) and were of reagent grade. RP Trimax x-ray film was purchased from Eastman Kodak Company (Rochester, NY).

Platelet Donors

RG, a 17-year-old male, had bruised extremities at birth and a subsequent history of gingival bleeding. Glanzmann's thrombasthenia was diagnosed at age 1½ years. Laboratory evaluation showed bleeding time >15 minutes; clot retraction 21%; a platelet count of 193×10^9/L; and platelet aggregation absent with ADP, epinephrine, thrombin, and collagen. Parent SJ has no history of a bleeding disorder.

BL, a 5-year-old male, has had easy bruising since age 9 months. Glanzmann's thrombasthenia was diagnosed at age 2 years. Laboratory evaluation showed bleeding time 9.5 minutes; a platelet count of 280×10^9/L; and no aggregation to ADP, collagen, or epinephrine. He is the offspring of a consanguineous sibling relationship. Parent DL has no history of a bleeding disorder.

Patient EA, a 34-year-old female, has been described in an earlier publication.[3] Laboratory evaluations have shown a prolonged bleeding time; normal platelet count and morphology; impaired clot retraction; and aggregation absent with ADP, thrombin, collagen, or epinephrine.

Antiplatelet Antibodies

An antihuman platelet membrane glycoprotein IIbβ monoclonal antibody (GTB18) was used as a specific probe for human platelets. The preparation and characterization of this monoclonal antibody was described previously.[4] Heterologous Protein A affinity-purified rabbit antihuman platelet glycoprotein IIb-IIIa antibody was kindly

provided by Dr David R. Phillips, Gladstone Foundation Laboratories (San Francisco, Calif). This antibody was demonstrated to be specific for glycoproteins IIb and IIIa by immunoprecipitation of solubilized platelet membranes and by the Western blot procedure using solubilized membranes or solubilized washed platelets electroblotted onto nitrocellulose paper.[5]

Fluorescein-conjugated (FITC) goat antirabbit and rabbit antimouse immunoglobulin were obtained from Sigma Chemical Co and had fluorescein-to-protein ratios of 4.7 and 4.2, respectively.

Preparation of Platelets

Venous blood from normal adult donors was collected by venipuncture through a 19-gauge needle and mixed with 0.16 volume of a solution containing 0.085 mol/L sodium citrate, 0.111 mol/L dextrose, and 0.071 mol/L citric acid (ACD). Donors took no medication for 2 weeks prior to blood collection.

The blood was centrifuged at 160 × g for 20 minutes, and the platelet-rich plasma removed. The platelets were separated from the plasma and washed twice in CGS buffer containing 0.12 mol/L sodium chloride, 0.013 mol/L trisodium citrate, and 0.03 mol/L dextrose, pH 7.0.[6] The platelets were washed a final time in TS buffer containing 0.154 mol/L sodium chloride, 0.01 mol/L Tris, and 0.0001 mol/L leupeptin, pH 7.4. The platelets were suspended in TS buffer for surface labeling. All procedures were conducted at room temperature.

Iodination of Platelet Surface Proteins

Platelets were radiolabeled with ^{125}I by lactoperoxidase-catalyzed iodination using a previously published procedure.[7] Washed platelets were solubilized in 2% SDS (w/v) containing 2% 2-mercaptoethanol (v/v) incubated at 100 °C for 10 minutes to assure solubilization. Protein (10 to 50 μg) was electrophoresed through slab gels according to the method of Laemmli[8] by using a 5% to 20% expontential gradient of acrylamide in the resolving gel and 3% acrylamide in the stacking gel. Protein was stained by Coomassie brilliant blue. For determination of the distribution of radioactivity, the gels of radiolabeled platelets were dried under vacuum on filter paper and stored next to RP Trimax x-ray film. After 24 to 72 hours exposure, the film was processed according to manufacturer's instructions. The relative amount of radioactivity in glycoproteins IIb and IIIa was determined by integration of the peaks corresponding to the glycoproteins from scans of autoradiographs using a GS 300 Transmittance/Reflectance scanning densitometer interfaced with an Apple IIc computer for analysis (Hoefer Scientific Instruments, San Francisco, Calif).

Preparation of Samples for Flow Cytometry

Platelet-rich plasma preparation. Platelet-rich plasma (PRP) from freshly drawn blood was collected by low-speed centrifugation at 800 × g and then diluted 1:1 (v/v) with CaTS buffer (0.154 mol/L sodium chloride, 0.01 mol/L Tris, and 0.0005 mol/L calcium chloride, pH 7.4) containing 50 μmol/L prostacyclin (PGI_2). To 200 μl PRP-CaTS, an antihuman platelet membrane glycoprotein monoclonal antibody (2 μg) was added and incubated for 30 minutes at room temperature (22 °C). The addition of two micrograms of antibody was shown to be saturating for the number of platelets in the sample. FITC-conjugated rabbit antimouse IgG (10 μg) was added and incubated for 10 minutes.

Preparation of whole human blood. Fresh human blood was diluted 1:1 (v/v) with CaTS buffer containing 50 μM PGI_2. Within 1 hour of venipuncture, the antiglycoprotein IIb and IIIa antibody (10 μg) was added to 400 μL of blood-CaTS and incubated for 30 minutes at room temperature. FITC-goat antirabbit IgG (40 μg) was added and after 10 minutes, the cells were analyzed by flow cytofluorimetry. Control experiments for both PRP and whole blood studies were treated in an identical manner except that buffer or a species-specific IgG (2 μg) was added instead of the antiplatelet antibody.

Flow cytometry. A Coulter EPICS V flow cytometer (Coulter Electronics, Inc) equipped with a Spectra Physics 164-05 argon ion laser adjusted to deliver 800 milliwatts at 488 nm was used to analyze platelets. Cells in suspension were analyzed at a flow rate of approximately 1,000 cells/sec. Forward-angle light scatter (1° to 19°) was converted from linear to logarithmic scale by using a log amplifier of the instrument. Fluorescein fluorescence emission was detected after passage through a 510 nm long pass interference filter to exclude scattered laser light. The light scatter and green fluorescence signals from each cell were collected from 50,000 cells and stored and analyzed by the Coulter MDADS minicomputer analysis system as two-parameter 64 × 64 channel histograms. Routinely, the fluorescence signals measured were gated on a light-scattering profile that excluded contributions from debris. Data (log light scatter *v* log green fluorescence signal *v* cell number) were transferred to a Data General MV8000 computer and accompanying Techtronics 4662 plotter for subsequent graphics.

RESULTS

Antibody binding to platelet membrane glycoproteins was assessed by fluorescence microscopy. Using standard fluorescein filter combinations for fluorescence microscopy, platelets plus antiplatelet glycoprotein IIbβ monoclonal antibody and FITC-rabbit antimouse IgG fluoresce strongly over background (platelets plus FITC-rabbit antimouse IgG alone). The labeling pattern of the antibody was uniform over the surface of the platelet as would be expected for a labeled major membrane component that is evenly dispersed (data not shown). A similar labeling pattern was observed when the platelets were reacted with heterologous antiglycoprotein IIb and IIIa antibody and FITC-goat antirabbit antibody.

To identify platelets on the basis of their characteristic cell size, unlabeled platelets in plasma were subjected to flow cytometric analysis on the Coulter EPICS V cytometer. Fifty thousand cells were analyzed simultaneously for size by low-angle log light scatter measurements. The platelets had a broad distribution of light-scattering signal which is indicative of size heterogeneity.

Once light scatter parameters for platelets were established, unlabeled and antibody-labeled cells in platelet-rich plasma were analyzed by flow cytofluorimetry. Figure 1 illustrates the fluorescence of the platelet population labeled with both the antiglycoprotein IIbβ and the species-specific FITC-conjugated antibody. Very little green fluorescence was associated with the platelets when only the FITC-conjugated rabbit antimouse antibody was added to the platelet sample indicating that nonspecific binding of this antibody was minimal. Experiments where preimmune mouse IgG was added rather than buffer as the control showed minimal nonspecific binding as well and did not alter the results. The mean fluorescence associated with the platelets in Fig 2 was 13 times that observed in the control experiment. Integration of the fluorescence signal determined that >98% of the cells analyzed as platelets were positive for bound antibody.

Figures 2A and 2B are two-parameter histograms from

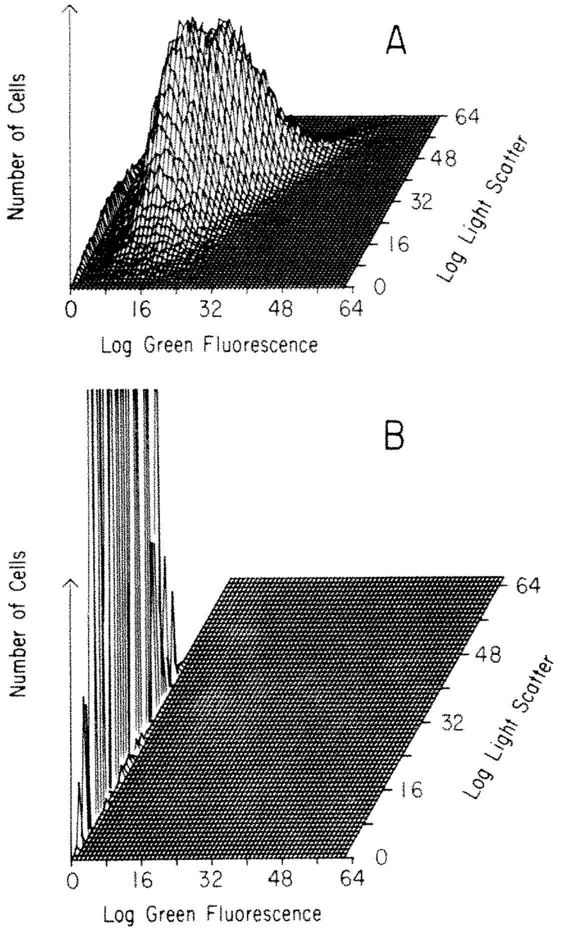

Fig 2. Two-parameter analysis of flow cytofluorimetry of platelets in PRP after addition of 2.5 μg of MoAb18 and FITC-rabbit antimouse IgG (Panel A). The control (Panel B) is of platelets treated in an identical manner except MoAb18 was omitted from the incubation medium. x-axis, log green fluorescence; y-axis, log light scatter; z-axis, number of cells.

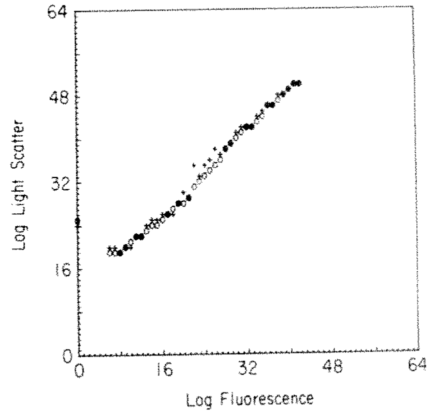

Fig 3. Data in Fig 2, Panel A, replotted as the peak (+) and mean (O) channel of fluorescence for each light scatter channel.

analyses of antibody-labeled cells and unlabeled control cells. In both samples, the platelets had a broad distribution of light scatter similar to that observed in one-parameter light scatter profiles. Platelets treated with mouse IgG or with only the FITC-conjugated rabbit antimouse IgG had no detectable fluorescence over background as all cells were contained in the first three channels of the x-axis. The fluorescence associated with the antibody-treated platelets was significantly greater than background as demonstrated in Fig 2 and was variable depending on the degree of the platelets' light scatter signal. A cursory examination of these data suggests that the larger platelets (those with higher light scatter signal) have a greater mean content of glycoprotein IIbβ than do smaller platelets. This observation is verified by plots of the peak (+) and mean (O) channel of fluorescence for each light scatter channel. As the platelet size increases, the fluorescence (and thus the total content of glycoprotein IIbβ per platelet) increases in a linear relationship (Fig 3).

We next sought to examine normal platelets in whole blood preparations using heterologous antibody directed against glycoproteins IIb and IIIa in a system incorporating unwashed cells, thus avoiding any alterations or artifacts due to cell washing or centrifugation. Platelets were first distinguished from other blood cells on the basis of light scatter. Figure 4 is the log light scatter profile of whole human blood

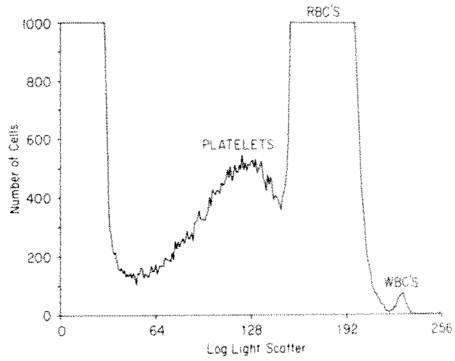

Fig 4. Log light scatter profile of whole human blood-containing platelets (peak 1) and erythrocytes (peak 2) and white blood cells (peak 3). x-axis, log light scatter; y-axis, number of cells.

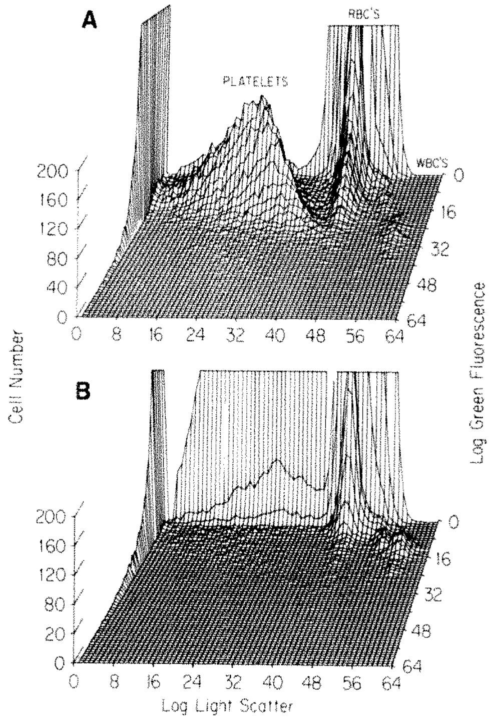

Fig 5. Two-parameter analysis of platelets in whole human blood after addition of anti-GPIIb-IIIa and FITC-conjugated goat antirabbit IgG (Panel A). containing platelets, erythrocytes, and white cells. Once the platelets were identified in whole blood, rabbit antiglycoprotein IIb and IIIa antibody and FITC-conjugated goat antirabbit immunoglobulin were added to whole blood as described in Materials and Methods, and the platelets were analyzed on the basis of light scatter and green fluorescence. Fifty thousand platelets were analyzed by collecting data based on log green fluorescence gated on light scatter profile for the platelet population. Figure 5A is the two-parameter histogram of whole blood after addition of antibodies with the corresponding plot of control cells (minus first antibody addition) in Panel B. Platelets were easily distinguishable in whole blood preparations and were specifically labeled by the antiglycoprotein IIb and IIIa antibody. The fluorescence intensity of the antibody-labeled cells was compared to the control group in Fig 6. The log green fluorescence of the antibody-treated platelets was approximately 4 to 5 times higher than that observed with the untreated or control platelet group (plus buffer or normal rabbit IgG instead of the antiglycoprotein IIb and IIIa antibody). Fluorescence of both the red cell and white cell populations appears increased in the antiglycoprotein IIb and IIIa antibody-treated whole blood. While a finite number of platelets were analyzed by collecting data gated on the light scatter profile for platelets, the number of red cells analyzed was different in the control and antibody-treated groups. In the experiment depicted, 56% more red cells were analyzed in the antibody-treated sample than in the corresponding control. Thus, what appears to be an apparent increase in RBC fluorescence is due to increased numbers of red cells being analyzed and not due to specific binding of the antiglycoprotein IIb and IIIa antibody. In contrast, the increased fluorescence observed in the white cell population is due to the detection of bound platelets to monocytes (manuscript in preparation) and is the

result of specific binding of the antiglycoprotein IIb and IIIa antibody to these adherent platelets.

This system was then extended to analyze glycoprotein IIb and IIIa content in Glanzmann's thrombasthenic individuals. These values were compared to the levels of glycoproteins IIb and IIIa present in a Glanzmann's thrombasthenic individual's platelets determined by scanning densitometry of autoradiograms of gels of ^{125}I-labeled surface proteins. Two parents of Glanzmann's thrombasthenia patients were included in this study.

Figure 7 is a densitometry scan of radiolabeled platelet surface proteins separated on SDS polyacrylamide gels from patient RG, his parent (SJ), and a representative normal donor. Integration of the peak corresponding to radiolabeled glycoproteins IIb or IIIa of patient RG showed 5.7% of the normal amount of glycoproteins IIb and IIIa (Table 1). The parent had approximately 73% of the normal amount. Patients BL and EA had approximately 33% and 2%, respectively, while DL (parent of BL) had approximately 61% of the normal levels of glycoproteins IIb and IIIa (Table 1).

Platelets were analyzed in whole blood from these individuals by flow cytometric techniques. The histograms of log green fluorescence versus cell number for RG, SJ, and a normal donor are illustrated in Fig 8. Figure 9 is the two-parameter analysis of the same individuals. Individual EA had essentially no detectable levels of glycoprotein IIb and IIIa with a relative fluorescence intensity (RFI) 1.4 times that of untreated platelets, whereas platelets from RG, BL, SJ, and DL and a normal donor had a RFI of 1.7, 2.3, 3.0, and 4.0, respectively (Table 1). Relative fluorescence intensity was determined by using the mean channel of log green fluorescence. These determinations are comparable to glycoprotein IIb and IIIa levels quantitated by autoradiography in that there is a high correlation (r = 0.98) of these levels to the RFI values calculated for each individual (Fig 10). The plot of this data would be expected to intersect at a RFI value of 1.0. The intersection at a slightly higher RFI value is due to the fluorescence associated with nonspecific antibody binding and the inherent autofluorescence of the platelets.

Flow cytometric analysis also permitted us to determine the uniformity of this defect in all individuals tested. The decreased amount of glycoprotein IIb and IIIa was homogeneous within the entire population of analyzed cells confirming that Glanzmann's thrombasthenia affects all platelets in circulation.

DISCUSSION

A variety of biochemical techniques have been used to study the structure of platelet membrane glycoproteins IIb and IIIa and to determine their function in platelet aggrega-

tion. Analysis of these membrane glycoproteins has been based primarily on the development of surface-labeling techniques.[9] Alternative immunochemical methods such as radioimmunoassay (RIA) and crossed immunoelectrophoresis (CIE) have been used to identify and quantify specific platelet surface receptors.[10,11] These methods provide ways of identifying the specific glycoprotein epitopes involved in mediating platelet functions. Studies by Nurden et al[12] have demonstrated that analysis by the immunoblot procedure detected residual amounts of platelet glycoproteins IIb and IIIa which were not initially observed by other methods such as CIE or SDS polyacrylamide gel electrophoresis.

All of these techniques demand a relatively large homogeneous platelet population that requires manipulation through isolation and washing procedures before analysis. Such manipulations may alter the expression or accessibility of surface components and involve considerable preparation time. Recent studies have shown that the association of these glycoproteins is dependent on the buffer and incubation conditions employed. For example, prolonged incubation of platelets or isolated membranes in the presence of EDTA will cause formation of glycoprotein oligomers that cannot be dissociated readily.[13]

We used antibodies that bind to membrane glycoproteins IIb and IIIa to develop methods for analyzing platelets in an unwashed preparation by flow cytometry and to determine if differences in glycoprotein expression could be detected by these methods. We were able to distinguish between Glanzmann's thrombasthenic individuals and carriers for the disorder. We also showed a high correlation between the RFI of the antibody-labeled platelets and the amount of glycoproteins IIb and IIIa analyzed by autoradiography of ^{125}I-labeled platelet proteins.

Platelets in platelet-rich plasma and whole blood were identified by their low-angle log light scatter profile. Although in whole blood preparations there was some overlap in the light scatter distribution of erythrocytes and platelets, erythrocytes can be gated out for platelet analysis or specific probes for platelets can be used in conjunction with their light scatter characteristics. Therefore, flow cytometry is an excellent technique for analyzing platelet surface proteins on a single cell basis. While clinically diagnosed Glanzmann's thrombasthenia patients have variable amounts of glycoproteins IIb and IIIa on their platelet membrane surface, we found that all platelets from each of these individuals were affected equally and that this disorder is not due to distinct populations of circulating platelets. Evaluation of platelets at the single cell levels by flow cytometry would be particularly useful for analysis of acquired platelet disorders such as paroxysmal nocturnal hemoglobinuria (PNH) where distinct platelet populations may occur.[14]

Other investigators have reported using flow cytometry to examine platelet-specific proteins. Adelman and coworkers examined glycoprotein Ib content in washed and formaldehyde-treated human platelets.[15] Johnston and coworkers[16] recently reported their use of flow cytometric techniques to study the effect of diamide and iodoacetamide on the expression of platelet glycoproteins and on platelet aggregation. Their data support our earlier findings[17] that flow cytometry is an efficient method to examine platelet membrane components.

Flow cytometry is also suitable for clinical analysis of platelet surface defects. This technique eliminates the use of radiolabeling techniques and can be performed in conjunction with other surface marker studies. Flow cytometric analysis provides a reliable index of the relative quantity of glycoproteins IIb and IIIa on the platelet membrane. We have demonstrated with our studies of four individuals with various levels of these glycoproteins that the RFI values are comparable with the percentages of glycoproteins IIb and IIIa determined by autoradiography. This method for examining the expression of platelet surface antigens has clear advantages in that platelets may be studied with little or no manipulation and requires only μL quantities of material for analysis. Analyzing platelets in platelet-rich plasma or whole blood provides a milieu most like the in vivo situation. Therefore, the expression of specific epitopes in resting platelets versus activated platelets may be more rigorously and accurately examined by flow cytometric methods.

ACKNOWLEDGMENT

We wish to thank Ed Wingfield and Graydon Nelson for their capable assistance and Dr Gilbert C. White II for providing patient samples. We also thank Ms Linda Daniels for editorial assistance and Ms Pat Powell for manuscript preparation.

DDAVP Infusion in Five Patients With Type Ia Glycogen Storage Disease and Associated Correction of Prolonged Bleeding Times

By Gerald E. Marti, Margaret E. Rick, James Sidbury, and Harvey R. Gralnick

Five patients with glycogen storage disease type I (GSD-I) were evaluated for a bleeding diathesis and subsequently were given an infusion of 1-deamino-8-D-arginine vasopressin (DDAVP). Although platelet counts were normal or slightly elevated, the baseline template bleeding times were prolonged in four of the patients. Prothrombin times and activated partial thromboplastin times were normal, while ADP- and epinephrine-induced platelet aggregations were absent in the three patients tested. Ristocetin- and collagen-induced platelet aggregations were abnormal. Laurell and immunoradiometric determinations of the factor VIII-related antigen (vWf antigen) were decreased. Glyoxyl agarose gel electrophoresis of the patients' plasma revealed abnormal multimer patterns in four of the five patients. After the DDAVP infusion the platelet aggregation abnormalities persisted; however, the bleeding time and the von Willebrand antigen and activity corrected. We conclude that GSD-Ia patients may have a metabolically acquired form of von Willebrand's syndrome as well as an acquired intrinsic platelet defect, and that DDAVP may be useful in the management of bleeding in these patients.

GLYCOGEN storage disease, Type I (GSD-Ia), formerly known as von Gierkie's disease, is an autosomal recessive disease with a deficiency of glucose-6-phosphatase in the liver, kidney, and intestine.[1] It is characterized by hepatomegaly, hypoglycemia, lactic acidosis, hyperlipidemia, hyperuricemia, and a bleeding diathesis. The bleeding diathesis is associated with a prolonged bleeding time and a qualitative platelet defect, while clinically it is manifested by epistaxis and bleeding after invasive procedures or trauma. We have studied the effects of an infusion of 1-deamino-8-D-arginine vasopressin (DDAVP) in five patients with GSD-Ia and show that DDAVP consistently normalizes the prolonged bleeding time and corrects the abnormal values of the factor VIII complex and vWf activities.

MATERIALS AND METHODS

Patients. Five patients with GSD-Ia, previously diagnosed by liver biopsy and enzyme analysis, were admitted to the Clinical Center, NIH, for routine evaluation. Bleeding histories and routine laboratory studies were remarkably similar; all had a history of bruising, epistaxis, bleeding with surgical and dental procedures, and a prolonged bleeding time (Table 1). There were no reported incidences of increased infections.

Coagulation assays. Blood (10 mL) was collected into polypropylene tubes (17 × 100 mm, Falcon) containing 0.1 mL of sodium citrate (32% solution). The tubes were placed on ice and plasma obtained by centrifugation for 10 minutes at 2,000 g at 4 °C. Aliquots were stored frozen at −70 °C.

Prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time (TT), and fibrinogen were determined by previously described methods.[2] Factor VIII coagulant activity (VIII:C) was measured in a one-stage assay, factor VIII coagulant antigen (VIII:CAg) by radioimmunoassay,[3] factor VIII-related antigen or vWf antigen by both Laurell and radioimmunoassay,[4] and ristocetin cofactor activity by macroscopic agglutination of fixed platelets.[5] Von Willebrand factor (vWf) multimeric organization was assessed by glyoxyl agarose electrophoresis and autoradiography.[6] Platelet aggregation with patients' platelet-rich plasma was performed with a lumi aggregometer[7] using ADP (3.8 to 16.0 μmol/L), epinephrine (7.5 to 22 μmol/L), collagen (226 μg/mL), thrombin (0.24 U/mL), and ristocetin (0.43 to 1.74 mg/mL) as agonists. Bleeding times were determined using a hand-held, spring-loaded Simplate bleeding time device (General Diagnostics, Morris Plains, NJ).

Table 1. Clinical Summary of GSD, Type I Patients Receiving DDAVP

Patient (age/sex)	Bleeding History	Simplate Bleeding Time (min)	Platelet Count (× $10^3/\mu$L)	Aggregation Studies	PT (sec)	aPTT (sec)	TT (sec)	Fibrinogen (mg/dL)
LRT (22/f)	Severe epistaxis in childhood gum bleeding bleeding with minor surgery	>18	318	abnormal*	12.2	36.5	30.4	502
RSB (26/m)	epistaxis bleeding after dental surgery bleeding with trauma	10.5	384	abnormal*	12.7	36.3	37.2	1,072

DDAVP infusion. A single dose of DDAVP (0.3 μg/kg) was infused over 30 minutes in 50 mL of normal saline. A preinfusion baseline bleeding time and citrated blood sample were obtained from a distal site through an indwelling butterfly needle after discarding the initial 3 to 5 mL of blood. The bleeding time was performed and blood samples were again obtained at 30 minutes, one hour, two hours, and four hours following the infusion. Body weight, serum sodium, hematocrit, and platelet count were determined within 24 hours of completing the infusion. Consent was obtained from patients and/or parents after they were informed of the real and potential risks of this study.

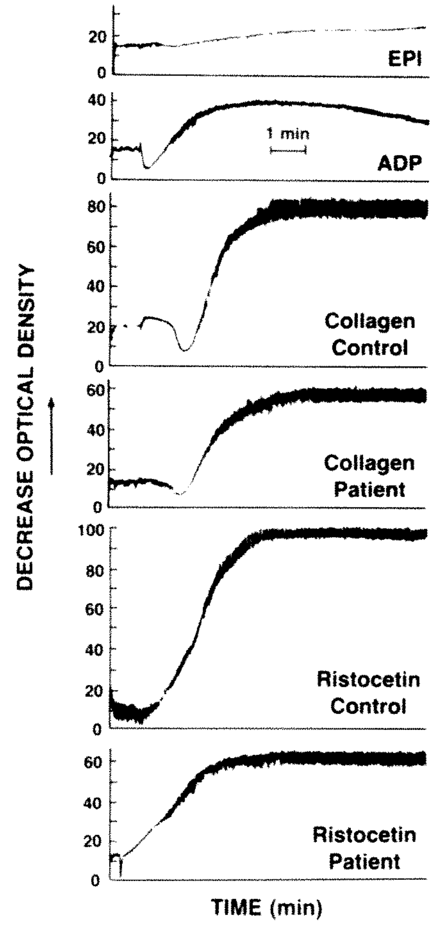

Fig 1. Representative platelet aggregation of PRP from a patient with GSD-Ia. In each experiment 400 μL of patient or normal platelet-rich plasma (200,000 platelets/μL) was incubated for three minutes at 37 °C prior to addition of the platelet agonist; it was stirred at 900 rpm. ATP release was measured by a leuciferase-leuciferin reaction; these tracings are not shown in the figure. Upper Panel: Epinephrine-induced platelet aggregation of the patient's PRP. Epinephrine at concentrations ranging from 7.5 to 21.9 μmol/L did not induce a second wave of platelet aggregation nor was there release of ATP. The control PRP (not shown) showed two waves of aggregation and release of ATP. The second panel is the ADP-induced platelet aggregation of the patient's PRP (ADP at 3.8 to 21.6 μmol/L). A single wave followed by disaggregation was observed. There was no ATP release. The normal PRP (not shown) had two waves of aggregation and released ATP at 4.5 μmol/L ADP. Panels 3 and 4 show the collagen-induced platelet aggregation of the control and the patient. The initial slope of aggregation of the control was much greater than the patient. Maximum collagen-induced aggregation was seen with both patient and control PRP at 242 μg/mL of collagen final concentration. The ristocetin-induced platelet aggregation of the control and patient is shown in the last two panels. The ristocetin concentration was 1.30 mg/mL and at this concentration the initial slope of the patient's PRP was reduced as was the total extent of aggregation. The initial slope of the normal control was 98 mm/min and that of the patient was 33 mm/min. Similar aggregation findings were seen in the other patients studied.

RESULTS

The five patients evaluated in this report all had clinical histories, physical findings, and laboratory values consistent with GSD-Ia and the diagnosis had been confirmed by liver biopsy and enzyme analysis. All five patients had histories of abnormal bleeding which was usually recognized by the age of 2 years and was most often reported as easy bruising and frequent severe nosebleeds. These symptoms became less pronounced by the time the patients became adolescents. Platelet counts were normal or slightly elevated in all patients, but four of five had prolonged template bleeding times (Table 1). The patients were in good metabolic control on multiple cornstarch feedings.

Initial coagulation parameters (PT, aPTT, TT) were normal in all patients except for elevations of fibrinogen. In patient RSB this had been noted five years previously and had been evaluated on numerous occasions by immunologic, biochemical, and chronometric methods; the results were concordant in all three assays. Of interest, this patient has a filling defect on a liver-spleen scan that is thought to be compatible with a benign adenoma.

All three patients tested had abnormal platelet aggregation with ADP and epinephrine. Little or no aggregation was noted with epinephrine while the secondary wave was absent with ADP. Two of the three patients (MPS, RSB) showed no response to low concentrations of ristocetin and had a decreased initial slope at all concentrations of ristocetin and collagen. Aggregation studies repeated after the DDAVP infusion showed no change. Figure 1 is a representative platelet aggregation study.

The responses in the bleeding times of four of five patients to DDAVP are shown in Fig 2. Of the five patients tested, all except one (JMK) showed a decrease in the baseline preinfusion bleeding time to normal. JMK's baseline bleeding time was nine minutes, and a one-hour post-DDAVP infusion bleeding time was eight minutes. By four hours post-DDAVP infusion, the bleeding time had returned to preinfusion values in all five patients. The effects of DDAVP upon VIII:C, VIII R:Ag, and vWf parameters are summarized in Tables 2 and 3. In general, there is a 2- to 4-fold increase in

all parameters evaluated. As was seen with the bleeding times, measurements of VIII:C and VIII R:Ag remained slightly elevated or had returned to baseline within the four hours following the DDAVP infusion.

Baseline vWf activity and VIII R:Ag were abnormal in three patients (LRT, DS, JMK; Table 3). In addition, plasma vWf multimeric patterns on glyoxyl agarose gel electrophoresis showed an abnormal pattern in four of the five patients. The patterns were characterized by a diffuse decrease of all multimers (JMK, moderate; DS, mild), or an apparent decrease in only the larger multimers (RSB, MPS). All five patients showed an apparent increase of the larger forms in their multimeric patterns following the DDAVP infusion, and on occasion a doublet was noted (seen best in the fastest migrating multimer). A composite autoradiogram is shown in Fig 3.

*Values for JMK's younger sister were ristocetin factor activity 85%, and for the Laurell and RIA determinations 48% and 34%, respectively.

DDAVP side-effects. During the DDAVP infusion four of the five patients showed facial flushing which they were unaware of, and one patient complained of vague abdominal cramping. No other side-effects were noted. There was no change in weight, hematocrit, or platelet count.

DISCUSSION

The occurrence of a bleeding tendency has been widely recognized in patients with GSD-Ia. It is usually recognized in early infancy and is characterized by easy bruising, severe nosebleeds, and prolonged bleeding following minor trauma, surgical or dental procedures.[8] However, bleeding with liver biopsy is unusual. Most investigators report a prolongation of the bleeding time despite normal platelet counts.[9-17] Lelong et al first demonstrated a qualitative platelet defect, and documented decreased prothrombin consumption and a retardation of platelet thromboplastin generation.[9] Although it was initially thought that platelets from patients with GSD-I had higher levels of glycogen and a deficiency of glucose-6-phosphatase, this observation has not been confirmed.[13,16]

We have studied five patients with type GSD-Ia. We found abnormal platelet aggregation, prolonged bleeding times, reduced VIII:RAg and vWf activity, and abnormal vWf multimer plasma patterns. In the present study, the VIII:C activity was normal in all individuals tested (Table 2). The ristocetin cofactor activity and VIII R:Ag levels were abnormally low in three of the patients (LRT, DS, JMK). The abnormalities in the multimer patterns showed either a diffuse decrease (DS, JMK) or an additional decrease in the largest multimers (RSB, MPS). These data indicate that some patients with GSD-Ia may have an acquired von Willebrand syndrome or a syndrome that mimics vWd.

Our five patients with GSD-Ia were given DDAVP intravenously. During the ensuing four hours after infusion, we observed an increase to normal levels of VIIIR:Ag in all patients and a correction of the bleeding time in four of five patients. The multimer patterns of plasma vWf showed an increase in all multimers and the appearance of larger multimers in those plasmas that were previously deficient.

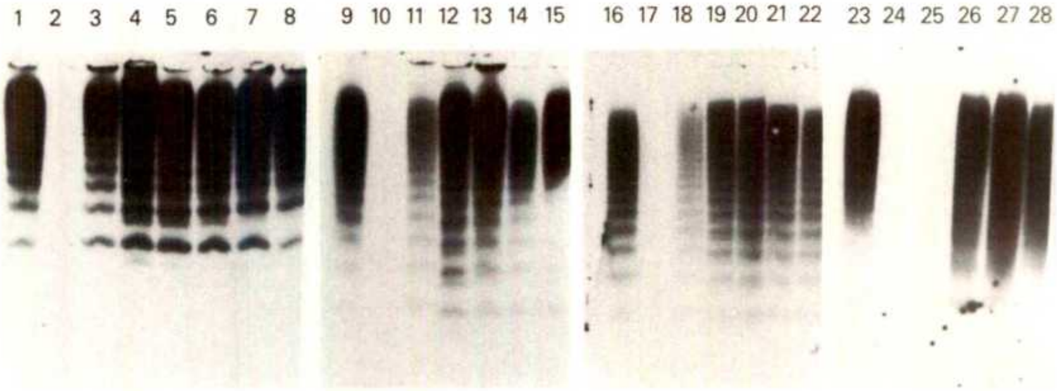

Fig 3. Composite summary of glyoxyl agarose gel electrophoresis autoradiographs before and after an infusion of DDAVP in five patients with GSD-Ia. Lanes 1, 8, 9, 16, and 23 contain normal pooled plasma. Lanes 2, 10, 17, and 24 contain plasma from an individual with severe von Willebrand's disease. Lanes 3 through 7 are pre-DDAVP (baseline), post-DDAVP 30', one hour, two hours and four hours, respectively, in patient LRT. Lanes 11 through 13 are pre-DDAVP, post-DDAVP 45' and two hours, respectively, in patient MPS. Lanes 14 and 15 are pre-DDAVP and post-DDAVP 30' in patient RSB. Lanes 18 through 22 are pre-DDAVP, post-DDAVP 30', one hour, and two hours, respectively, in patient DS. Lanes 25 through 28 are pre-DDAVP, post-DDAVP one hour, two hours, and four hours, respectively, in patient JMK. Although no radioactivity is appreciated in lane 25 of the photograph, reduced multimers were seen on the autoradiograph.

DDAVP presumably causes the release of vWf multimers including high molecular weight multimers from endothelium and/or other storage sites.[18,19] In patients with type I and type IIa vWd this is associated with a transient shortening or normalization of the bleeding time, and in vitro perfusion studies have shown increased platelet adherence and platelet aggregate formation.[20] The five patients examined in this report all responded to DDAVP in a manner similar to that seen in patients with vWd, hemophilia A, uremia, and dysfunctional platelet syndromes.[21-28]

In vitro platelet function studies have demonstrated the absence of a secondary wave in ADP- and epinephrine-induced platelet aggregation, while with collagen and ristocetin the response is diminished.[13-15] Platelet adenine nucleotide levels may be normal or reduced and the defective release of ADP remains to be confirmed.[13-15] Reports of mixing experiments involving GSD-I plasma and its effect upon normal platelet aggregation are contradictory.[13,14,17] Early attempts to characterize the mechanism of the platelet dysfunction examined the relationship between the prolonged bleeding times and metabolic abnormalities: hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Several investigators[13-15,29] have shown that infusions of glucose, intravenous hyperalimentation, and total parenteral hyperalimentation can lead to correction of the bleeding times and in vitro platelet function. However, it would appear that several days (10 to 12) of this therapy are required before normalization occurs.[14] Portacaval shunting can result in the long-term correction of these abnormalities.[14,24]

Kao et al reported impaired ristocetin-induced platelet aggregation in six children with GSD-Ia.[17] Studies with washed platelets indicated a plasma abnormality rather than an intrinsic platelet defect, and binding studies revealed a normal number of VIII:RAg receptor sites on GSD-Ia platelets. Further studies suggested that the fibrinogen from GSD-Ia plasma was inhibiting ristocetin-induced agglutination in these patients. A posttranslational modification of the carbohydrate in fibrinogen could occur in plasma of GSD-Ia patients which might account for this phenomenon[30]; further analysis of our patients' fibrinogens is being carried out.

The present study confirms previous reports of abnormal platelet aggregation in conjunction with prolonged bleeding times in patients with GSD-Ia. The data also indicate a probable high incidence of decreased vWf levels and activity in these patients. Regardless of the nature of the defect(s), our data demonstrate that GSD-Ia patients responded to DDAVP in a predictable manner, and suggest that DDAVP may be efficacious in the treatment of bleeding episodes or treatment prior to minor surgical procedures in these patients.

Synthesis of Eosinophil-Associated Enzymes in HL-60 Promyelocytic Leukemia Cells

By Steven A. Fischkoff, Glenn E. Brown, and Avrom Pollak

Eosinophils derived from HL-60 cells share many of the abnormalities of granule histochemistry and morphology frequently seen in eosinophils of patients with certain malignancies, especially those seen in acute myelomonocytic leukemia with abnormal eosinophils (FAB class M4eo). In order to understand the pathogenesis of these abnormalities, four enzymes, characteristic of the eosinophil, were studied in HL-60 promyelocytic leukemia cells at various stages of eosinophilic differentiation. Using biochemical and ultrahistochemical techniques, the following differences from normal eosinophil development were demonstrated. First, both myeloperoxidase and eosinophil peroxidase coexisted in the population of maturing HL-60 eosinophils. Second, the granules formed from the condensation of material in vacuoles which were derived from dilated segments of the endoplasmic reticulum; the role of the Golgi apparatus in processing of peroxidase appeared minimal. Third, low levels of lysophospholipase and arylsulfatase were present in the cells compared to normal eosinophils. Finally, crystallizations resembling precursor structures of Auer rods appeared in the granules of about 5% of the cells. These findings suggest that several disorders of the control of protein synthesis and processing exist in HL-60 eosinophils which may be responsible for the abnormal granule morphology and histochemistry.

MORPHOLOGICALLY and histochemically abnormal eosinophils have been described in a variety of disease states, notably lymphoid and myeloid malignancies.[1-4] Alterations in the pathways by which granule proteins and enzymes are processed and packaged in myeloid precursors have been documented in certain of these disorders.[1,5] For example, little stainable peroxidase activity could be demonstrated in the Golgi apparatus in myeloid precursors from patients with acute nonlymphocytic leukemia despite abundant stained material in the endoplasmic reticulum and granules.[5,6] In normal eosinophils the Golgi apparatus is intrinsically involved in peroxidase processing.[7] Because the pathways for protein synthesis and processing have been studied in detail in normal eosinophil precursors,[7,8] careful examination of these pathways in the abnormal immature eosinophils should clarify the pathogenesis of the granular abnormalities.

Our finding that the HL-60 cell line appears to be a model for a recently recognized subset of acute myelomonocytic leukemia (FAB class M4eo), characterized by the presence of dysplastic bone marrow eosinophils and chromosomal break at 16q22, provides an opportunity to study these pathways in a controlled, in vitro model system.[9] In particular, both the HL-60 eosinophils and the bone marrow eosinophils of these patients share the following features of their granules: they are frequently large in size and irregular in shape; they stain variably from red to blue with the Wright stain, even in the same cell; crystalloids are absent; and the Periodic acid-Schiff (PAS) and chloroacetate esterase reactions are positive (normal eosinophil granules are negative for both).[4,9] Since similar granule abnormalities have also been observed in eosinophils of patients with other cancers, the underlying mechanistic alterations present in acute nonlymphocytic leukemia with abnormal eosinophils (ANLL-M4eo)[2] patients may also be operative in these other diseases with abnormal eosinophil granules. Therefore, characterization of the pathway of granule protein processing in HL-60 cells induced to differentiate to eosinophils, and comparison to that described in normal eosinophils should lead to an improved understanding of the pathogenesis of the abnormal eosinophil granules in ANLL-M4eo and possibly of other malignant diseases.

MATERIALS AND METHODS

Cell culture and inductions. HL-60 cells were cultured in RPMI-1640 with 10% heat-inactivated fetal calf serum (K.C. Biological, Lenexa, Kan) and penicillin and streptomycin (50 IU/mL and 50 ug/mL, respectively, Flow Laboratories, Rockville, Md; "complete medium") in a humidified atmosphere of 5% carbon dioxide. Cell cultures to be used for eosinophil inductions were grown differently from those used for neutrophil inductions.[10] The eosinophil-destined cultures were subcultured on Fridays to a concentration of 5×10^5 cells/mL with complete medium adjusted to pH 7.6 to 7.7 with NaOH. On Mondays, an equal volume of this medium was added. On Tuesdays, Wednesdays, and Thursdays the flasks were removed from the incubators until the pH rose to 7.6 (approximately two hours for T-75 flasks; Corning, Corning, NY). After culturing in this fashion for at least two months, eosinophilic differentiation was induced by suspending these cells at 5×10^5 cells/mL in complete medium at pH 7.4, adding 0.5 mmol/L butyric acid (as a 0.5 mol/L stock solution in ethanol, Sigma, St Louis) and incubating the flasks for seven days without further attempts at controlling medium pH. Cells used for neutrophil inductions were subcultured on Fridays to a concentration of 5×10^5 cells/mL with complete medium adjusted to pH 7.2 to 7.3 and fed with an equal volume of complete medium on Mondays. No further measures were performed to control pH. For neutrophil inductions, these cells were suspended at 5×10^5 cells/mL in complete medium containing 176 mmol/L dimethylsulfoxide (DMSO; Aldrich Gold Label, Aldrich, Milwaukee), and the cultures incubated for seven days. The extent of differentiation was assessed by differential counts of Wright-stained cytospin preparations.

Electron microscopy. Cells were fixed for one hour in either 4% formaldehyde-1% glutaraldehyde in phosphate buffered saline (for peroxidase staining) or 2% glutaraldehyde in cacodylate buffer (for acid phosphatase, arylsulfatase, and lysophospholipase staining). Peroxidase activity was localized using 3:3′-diaminobenzidine (Sigma; see reference 11). Acid phosphatase activity was localized with β-glycerophosphate or p-nitrophenyl phosphate (Sigma; see reference 12). Arylsulfatase activity was localized with p-nitrocatechol sulfate (Aldrich; see reference 13) and lysophospholipase with lysophosphatidylcholine (Sigma; see reference 14). Cell pellets were embedded, sectioned, and examined with a JEOL 100CX electron microscope.

Enzyme extractions and assays. For each assay, 1×10^7 cells were washed and suspended in 1 mL of lysis buffer and sonicated for three minutes at Power Level 6 in a bath-type sonicator (Heat Systems W-225R). The compositions of the lysis buffers, substrates, and references for assay methods are given in Table 1. Oxidized minus reduced difference spectra for myeloperoxidase and eosinophil peroxidase were obtained using sodium dithionite as a reductant in an Aminco DW-2 double-beam spectrophotometer.[18] To examine the isoenzymes of acid phosphatase, the cell pellets were suspended in 0.2% (w/v) 3-(3-cholamidopropyl)dimethylammonio-1-propane sulfonate (CHAPS; Sigma) in 0.01 mol/L Tris-HCl, pH 7.4, to a final concentration of 2×10^8 cells/mL. The suspensions were sonicated at a setting of 7 for 40 seconds, followed by pelleting of the debris at 13,000 x g for three minutes at room temperature. Twenty μL samples were subjected to isoelectric focusing on Servalyte Precotes (pH 3 to 10, Serva) using a programmable power supply (Pharmacia ECPS 3000/150) as described by Serva. Activity bands were visualized with α-naphthol phosphate (Sigma) as a substrate and Fast Black K (Sigma) as the coupler.[19] Inclusion of 0.2% CHAPS in the extraction buffer increased the number of bands resolved and their intensities. Analysis of statistical significance was performed via the one-tailed student's *t* test.

RESULTS

Induction of differentiation. Over the course of a seven-day incubation with butyric acid, the HL-60 cells which had been previously cultured at pH 7.6 underwent differentiation to eosinophil-like cells. All induced cultures used for the enzymologic studies below consisted of no less than 50% eosinophils and no more than 20% neutrophils (balance of 100% was undifferentiated cells). Cells treated with DMSO for seven days underwent differentiation to neutrophil-like cells, albeit to a slightly lesser extent than that expected for HL-60 cells previously grown at pH 7.2. These cultures consisted of greater than 50% neutrophils (typically greater than 70%) and no more than 10% eosinophils (balance of 100% was undifferentiated cells). While the population of cells matured steadily in response to butyric acid, there was always cell-to-cell variability in the extent of maturation such that homogeneous populations of eosinophils at any particular level of maturation never existed. Nevertheless, on the electron photomicrographs, there was good morphologic correlation between the degree of nuclear maturation using criteria summarized by Wetzel (margination and condensation of chromatin, presence of nucleoli, nuclear size, and nuclear lobulation; reference 20) and the cytoplasmic changes described below. Thus, it was possible to use nuclear maturation as an internal clock by which to sequence cytoplasmic changes that occur with maturation in a mixed population of maturing cells. This approach has previously been used by Presentey et al.[1]

Peroxidase activity. Peroxidase activity was present in immature HL-60 cells populations and increased approximately 30% over seven days in untreated cultures (Fig 1). There was a steady decrease in enzyme activity per cell in DMSO-treated cultures beginning as early as the first day of culture until 45% of the initial peroxidase activity remained at the end of seven days. However, enzyme activity dropped at 24 to 48 hours and then increased above the baseline levels during the eosinophil induction with butyric acid (Fig 1). Because cell numbers increased in these cultures while enzyme activity per cell increased, new enzyme synthesis must have occurred.

We previously reported the presence of cyanide-resistant peroxidase activity in the HL-60 eosinophils using histochemical methods.[9] This implied that eosinophil peroxidase, which is a different molecular species than myeloperoxidase, was present. In order to more firmly establish which isoenzymes of peroxidase were present in the HL-60 eosinophils, difference spectra with and without reduction by sodium

Table 1. Enzyme Activity in HL-60 Cells in the Undifferentiated State and After Neutrophilic or Eosinophilic Differentiation

	Enzyme Activity†		
Enzyme*	Uninduced	Neutrophilic	Eosinophilic
Peroxidase (total)[15]	$0.398 \pm 7.1 \times 10^{-4}$	0.205 ± 0.088 (0.031)	$0.351 \pm 2.3 \times 10^{-4}$ (0.151)
Acid Phosphatase[15]	0.036 ± 0.045	0.421 ± 0.268 (0.027)	0.589 ± 0.036 (2.5×10^{-5})
Arylsulfatase[16]	0.135 ± 0.014	0.157 ± 0.070 (0.031)	0.235 ± 0.045 (0.011)
Lysophospholipase[17]	20.5 ± 2.4	61.8 ± 31.8 (0.046)	76.3 ± 51.4 (4.9×10^{-3})

HL-60 cells were cultured for seven days at an initial concentration of 5×10^5 cells/mL of complete medium in the presence of no addition (uninduced), 176 mmol/L DMSO (neutrophilic), or 0.5 mmol/L butyric acid (eosinophilic). Cells were harvested, sonicated in the lysis buffers (see footnote), and the extracts assayed for enzyme activity as per the given reference. Values given represent the mean of three values ± SD with the *P* value in parenthesis below.

*Lysis buffers: Peroxidase and acid phosphatase, 0.3% (w/v) Triton X-100 in H_2O; arylsulfatase, H_2O; lysophospholipase, Dulbecco's phosphate-buffered saline.

†Units: Peroxidase, ΔO.D. 560/1 min/10^6 cells; acid phosphatase, ΔO.D.405/2 h/2.5×10^5 cells (nonspecific activity in presence of 2 mmol/L NaF subtracted); arylsulfatase, ΔO.D. 515/1h/10^6 cells; lysophospholipase, counts per minute (above blank)/1 h/10^6 cells.

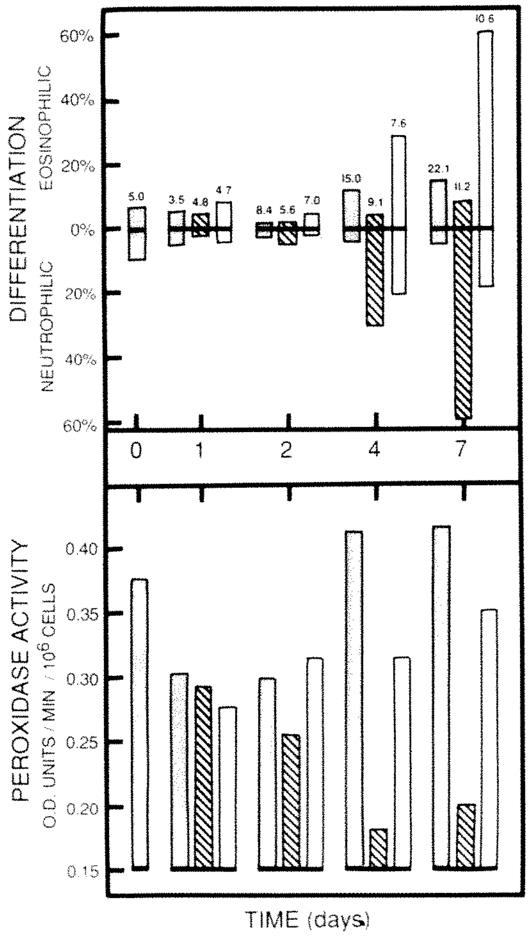

Fig 1. HL-60 cells, previously grown at pH 7.6, were suspended at 5 × 10^5 cells/mL in complete medium in the presence of no added compound (stippled bars), 176 mmol/L DMSO (cross-hatched bars), or 0.5 mmol/L butyric acid (open bars). Aliquots were removed at days 0, 1, 2, 4, and 7 for cell and differential counts (upper panel) and for assay of peroxidase activity (lower panel). The differential counts are presented as upward bars for cells with eosinophil granules and downward bars for neutrophils. Only cells with nuclei in the myelocyte, metamyelocyte, banded, or segmented stage of maturity were counted. Myeloblasts and promyelocytes represent the balance of 100%. The cell counts (× 10^{-5} cells/mL) are shown above the differential count bars. The peroxidase activity is expressed as the change in O.D. units per minute per 10^6 cells. All values represent the mean of 3 determinations (upper panel) or 5 to 6 (lower panel). Standard deviations did not exceed 20% for cells counts or enzyme activities.

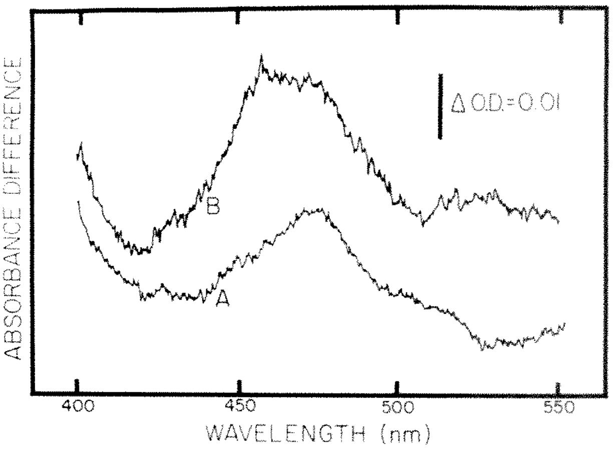

Fig 2. Extracts were prepared from uninduced HL-60 cells (trace A) and HL-60 eosinophils after seven days of culture with 0.5 mmol/L butyric acid (trace B) by sonication of 10^7 cells/mL in 0.3% Triton X-100 in water. Half of each sample was reduced with sodium dithionite and difference spectra obtained.

dithionite were obtained in a double-beam spectrophotometer using extracts before and after induction of eosinophilic differentiation (Fig 2). Uninduced cell extracts yielded a single peak at 474 nm corresponding to myeloperoxidase. HL-60 eosinophil extracts demonstrated an additional peak at 456 nm corresponding to eosinophil peroxidase in addition to the myeloperoxidase peak resulting in a broad plateau.

Peroxidase ultrastructural localization. HL-60 cells grown at pH 7.6 were treated with 0.5 mmol/L butyric acid for seven days, stained for peroxidase activity, and examined via the electron microscope. The least mature HL-60 cells demonstrated peroxidase activity in the endoplasmic reticulum and perinuclear cistern (Fig 3A). These cells lacked the peroxidase-positive primary granules usually seen in immature HL-60 cells grown at lower pH, thus being most similar to the myeloblast. With continued enzyme synthesis, dilatation of the endoplasmic reticulum occurred which filled with a granular, flocculant, peroxidase-positive material (Fig 3B). Vacuoles were found, seeming to arise from more markedly dilated segments of endoplasmic reticulum. These segments were also filled with the peroxidase-containing material. In cells with nuclei at the metamyelocyte stage of maturity (Fig 3C), peroxidase activity was again seen in the endoplasmic reticulum and, to a minor extent, in the Golgi apparatus. The vacuolar dilatations were more extensively developed. The material in the vacuoles underwent condensation, forming granules (Fig 3C, arrow). Vesicular budding of peroxidase-positive material from the Golgi apparatus could not be demonstrated. With continuation of the process of condensation of vacuole material into granules (Fig 3D), less enzyme activity was demonstrable in the endoplasmic reticulum and that in the perinuclear cistern virtually disappeared. The completed granules were not free in the cytoplasm but were membrane bound. The membrane probably represent the wall of the vacuole, now adherent to the granule. Further cellular maturity was associated with disappearance of enzyme activity from the endoplasmic reticulum so that all peroxidase activity was localized to the granules. In approximately 5% of cells, the granule proteins crystallized into randomly oriented tubules and multilammellar structures composed of peroxidase-positive subunits (Fig 4). Dixon et al suggested that such structures in leukemic promyelocytes represented precursors of Auer rods.[21] While elongated structures derived from intergranular fusion were found, fully developed, typical Auer rods were never observed.

Acid phosphatase. The level of acid phosphatase activity increased in response to a seven-day eosinophil induction with butyric acid (Table 1). Increased enzyme activity has been similarly reported with DMSO-induced neutrophil

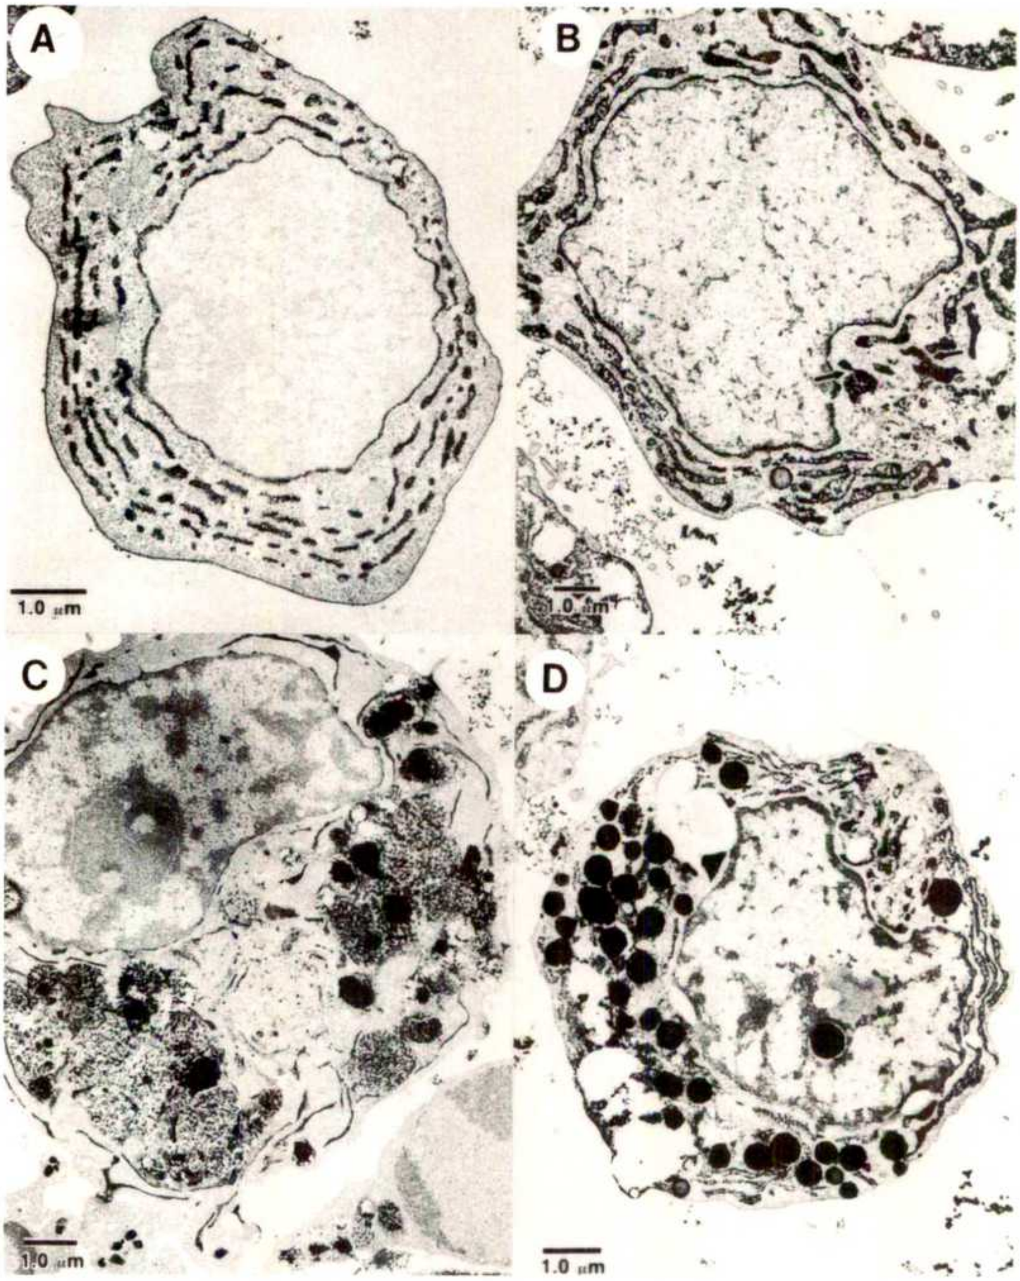

Fig 3. HL-60 cells previously grown at pH 7.6 were cultured for seven days with 0.5 mmol/L butyric acid, fixed, and stained for peroxidase activity. (A) This cell demonstrates the absence of primary granules and peroxidase activity in the endoplasmic reticulum and perinuclear cistern. Bar = 1.0 μm. (B) Dilatation of the endoplasmic reticulum into vacuoles filled with peroxidase-positive material is shown. Arrows point to areas where the vacuoles and endoplasmic reticulum are continuous. Bar = 1.0 μm. (C) Development of granules within vacuoles containing peroxidase-positive material is demonstrated. The Golgi apparatus is poorly stained for peroxidase activity despite easily seen activity in the granules and endoplasmic reticulum. Bar = 1.0 μm. (D) Virtual completion of granule formation has occurred. Enzyme activity has disappeared from the perinuclear cistern, although it persists in the endoplasmic reticulum. Bar = 1.0 μm.

differentiation and 12-O-tetradecanoylphorbol-13-acetate (TPA)–induced macrophage differentiation of the HL-60 cells.[12] Extracts of HL-60 cells, treated for seven days with either DMSO (neutrophil) or butyric acid (eosinophil), were subjected to isoelectric focusing and the gels stained for acid phosphatase activity. Thirteen bands were seen at identical isoelectric points ranging from 4.5 to 6.2. While some differences in intensity were seen between individual corresponding bands, no unique activities were observed in the HL-60 eosinophil extracts, nor were any activities seen in the DMSO-treated samples unrepresented. Some insoluble activity remained at the origin regardless of the use of Triton X-100 and/or CHAPS precluding estimates of the proportion of activity in each band.

Ultrastructure localization of acid phosphatase activity. Unlike peroxidase activity, acid phosphatase activity was not seen in the endoplasmic reticulum or Golgi apparatus of immature HL-60 eosinophils using either β-glycero-

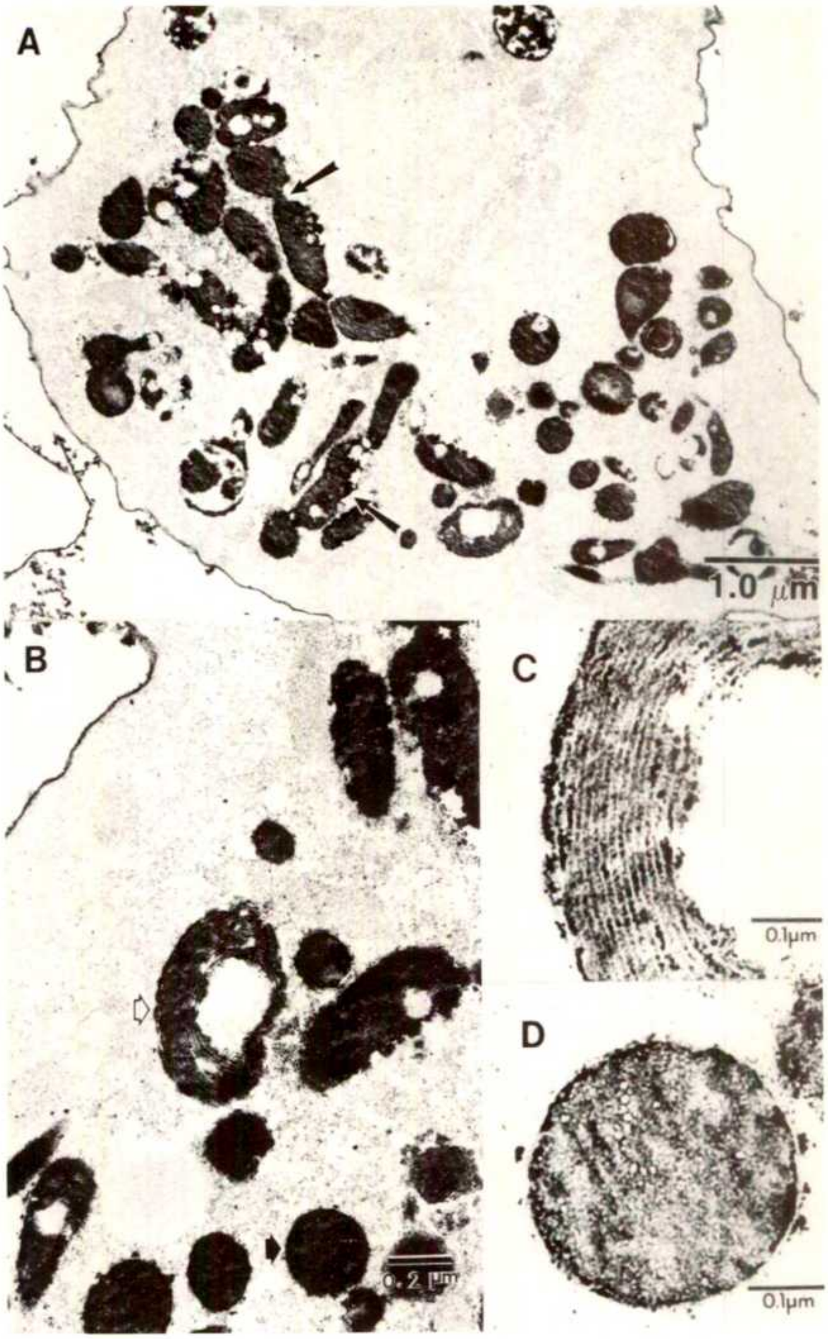

Fig 4. HL-60 cells grown and processed as in Fig 3 demonstrate completion of the process of granule formation and disappearance of peroxidase activity from the endoplasmic reticulum. In this cell, crystallization of granule proteins occurred yielding multilamellar structures and tubules composed of peroxidase-positive subunits. (A) Low magnification view demonstrates intergranular fusion, yielding elongated structures (arrows). Bar = 1.0 µm. (B) Detail of previous micrograph demonstrates peroxidase staining in areas where lamellar structures and tubules are developed. Bar = 0.2 µm. (C) High magnification of granule in B marked with open arrow demonstrates subunits in lamellae. Bar = 1.0 µm. (D) High magnification of granule in B marked with closed arrow demonstrated tubules in crosssection. Bar = 0.1 µm.

phosphate or p-nitrophenyl phosphate as a substrate. However, acid phosphatase–positive flocculant material was also found in many vacuoles and appeared to condense into granules. P-nitrophenyl phosphate, unlike β-glycerophosphate, can be used to demonstrate acid phosphatase activity in extralysosomal sites in mammalian cells.[12] This did not appear to be the case in the HL-60 eosinophils. As previously described for normal eosinophil granules,[22] condensation of acid phosphatase appeared to result in enzyme inactivation so that, often, only a rim of activity could be demonstrated around the granules (Fig 5A). This phenomenon was also seen in granules where the multilamellar structures formed (Fig 5B). Unlike peroxidase activity, in areas where the crystalline structure was poorly formed, enzyme activity was preserved; in areas where it was well formed, enzyme activity was greatly diminished or absent.

Arylsulfatase and lysophopholipase. Both of these enzymes were expressed in the HL-60 neutrophils and eosinophils (Table 1). However, eosinophils in peripheral blood smears from normal individuals and from a patient with hypereosinophilia secondary to a lung tumor showed considerably more intense staining for both enzymes than did HL-60 eosinophils at the light microscopic level. Ultrastructurally, minor deposits representing arylsulfatase activity could be seen at the surface of some granules if the sections were not counterstained. Deposits representing lysophospho-

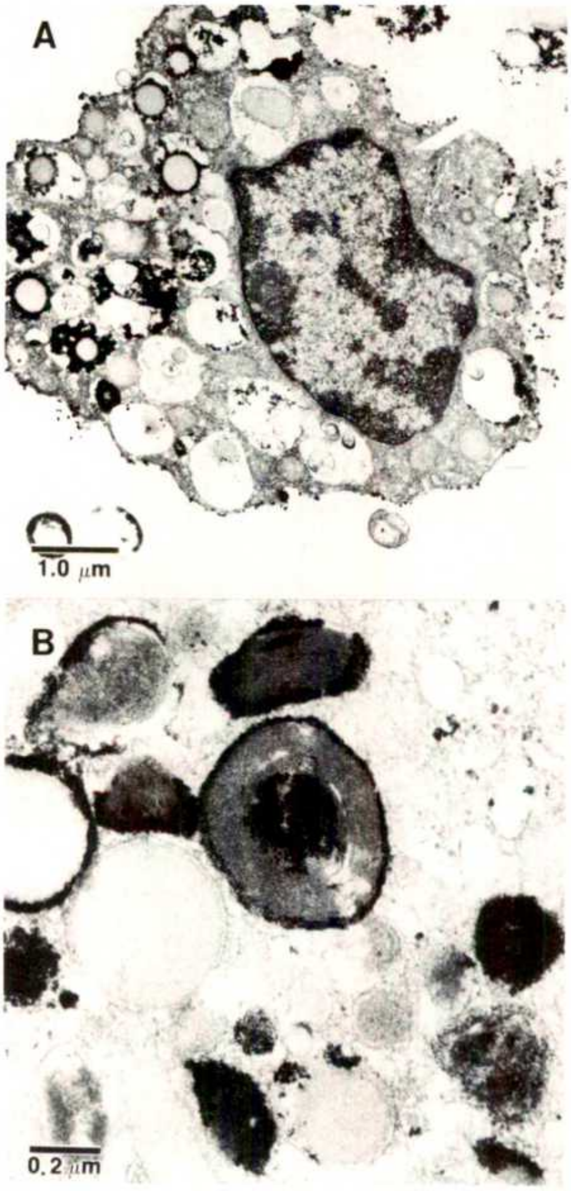

Fig 5. HL-60 cells were grown as in Fig 3, fixed, and stained for acid phosphatase activity using β-glycerophosphate. (A) Acid phosphatase-positive material is seen condensing into granules that no longer demonstrate enzyme activity. Bar = 1.0 μm. (B) Acid phosphatase activity has disappeared from areas undergoing crystallization to multilamellar structures, but is retained in adjacent, poorly crystallized area. Bar = 0.2 μm.

lipase activity were demonstrated in dilated segments of endoplasmic reticulum. However, for both enzymes, the deposits were not consistently found in all the HL-60 eosinophils.

DISCUSSION

In order to define the pathways by which the eosinophil-associated enzymes are expressed in HL-60 cells induced to differentiate to eosinophils, a combined approach was taken. First, the activities of these enzymes were measured in whole cell extracts at different time points during the induction of differentiation. In some cases, isoenzyme studies were performed. Second, enzyme activities were localized at the ultrastructural level using ultrahistochemical techniques at various stages of eosinophil maturity. This latter approach, previously used by others,[1] was made possible by the apparently constant relationship between the degree of maturity of the nucleus based on morphologic criteria and the degree of development of the cytoplasm. Although that relationship was not identical to that reported in normal eosinophil precursors, it was possible to use the nuclear morphology as an internal clock to confirm that observed changes in cytoplasmic morphology were indeed sequential.

Of the four enzymes studied, most information was gained from peroxidase. When HL-60 cells were induced to differentiate to neutrophils with agents such as DMSO, there was a progressive loss of peroxidase activity over the induction period. Koeffler et al[23] has shown this to be due to a cessation of synthesis of myeloperoxidase. On the other hand, when HL-60 cells were induced to differentiate to eosinophils, total peroxidase activity increased above baseline after an initial dip seen at 24 to 48 hours of induction. The appearance of a new spectral peak at 452 nm on the oxidized minus reduced difference spectrum of the extracts of HL-60 eosinophils demonstrated the presence of eosinophil peroxidase which was not present at the beginning of the induction. Because the peak at 474 nm is still seen at the end of the induction period, myeloperoxidase appears to be present at this point as well. Unfortunately, this approach does not lend itself to precise quantitation of the relative amounts of the two peroxidases. Whether the initial drop in total peroxidase activity represents some loss of myeloperoxidase with the latter increase in total activity representing new synthesis of eosinophil peroxidase must await future studies using alternative assay techniques. Nevertheless, this demonstrates qualitative, quantitative, and kinetic differences in the expression of peroxidase activity and its isoenzymes between HL-60 cells induced to differentiate to eosinophils and those induced to differentiate to neutrophils.

Cells at all stages of eosinophilic differentiation could be identified in electron photomicrographs of HL-60 eosinophils stained for peroxidase activity. The least morphologically mature cells, which clearly appeared to be the precursors for the more mature HL-60 eosinophils, stained for peroxidase activity only in the endoplasmic reticulum and the perinuclear cistern. Judging by the absence of cytoplasmic granules and the appearance of the nucleus, these cells corresponded most closely to myeloblasts. Although these immature cells demonstrated complete loss of the peroxidase-positive promyelocytic granules seen in the undifferentiated HL-60 cells, it is likely that the majority of HL-60 cells differentiating to eosinophils retain a portion of their promyelocytic granules. Our previous studies support this conclusion because toluidine blue staining in HL-60 eosinophils reveals the continued presence of promyelocytic granules in HL-60 cells with many eosinophilic granules by virtue of the former's metachromatic staining properties.[9] Furthermore, the observed decrease of peroxidase activity seen between 24 and 48 hours of induction (Fig 1) combined with the demonstration of myeloperoxidase activity (specific for promyelocytic granules) in the populations of HL-60 cells that have differentiated to eosinophils is consistent with partial loss of promyelocytic granules being typical.

As the cells continued to mature, further collection of flocculent peroxidase-positive material caused dilatation of the endoplasmic reticulum. Segments of the endoplasmic reticulum formed vacuoles enclosing this material. It then apparently condensed into spherical granules that remained peroxidase-positive. In some cases, a multilammelar crystallization of granule proteins formed that remained peroxidase-positive throughout the structure. These structures have been suggested by Dixon et al[21] to represent precursors of Auer rod formation in granules of acute promyelocytic leukemia cells. However, until typical, fully formed Auer rods are observed in HL-60 cells, firm identification of these structures as Auer rod precursors remains speculative.

In most sections of cells at all stages of maturation where Golgi apparatus can be visualized, little enzyme activity is seen within the structure. This observation must be interpreted with caution because microscopic observations can only demonstrate the presence of enzyme activity in a particular compartment, and in the absence of other data, cannot be used to draw kinetic or quantitative conclusions about the rates of passage of proteins through that compartment.[24] However, as sections of multiple cells have been taken, simultaneously showing abundant enzyme activity in the endoplasmic reticulum, vacuoles, and granules, with little in the Golgi apparatus, we conclude that the Golgi apparatus is not a major conduit of peroxidase from its point of synthesis to the granule. This conclusion is in agreement with Bainton et al[5] and Breton-Gorius and Houssay[6] who demonstrated decreased peroxidase staining of the Golgi apparatus in leukemic myeloid cells. Failure to observe formation of peroxidase-containing vacuoles budding from the Golgi apparatus is further evidence of lack of involvement of the Golgi apparatus in processing peroxidase before its transport to the vacuoles.

Scott and Horn have described a similar mechanism of granule formation.[25] In their study of normal eosinophil precursors, the endoplasmic reticulum segmentally dilated forming vacuoles that were partially filled with an electron dense matrix. They too noted little evidence of the Golgi apparatus packaging granule contents. However, neither they nor we unequivocally demonstrated a connection between the vacuoles and the endoplasmic reticulum once the granules began to form. Furthermore, it is impossible to exclude the possibility that both mechanisms (dilatation of segments of the endoplasmic reticulum containing preformed peroxidase, and transport of proteins through the Golgi apparatus) are simultaneously operative to variable extents. The recent demonstration that monensin can inhibit the processing of myeloperoxidase in normal eosinophils, but not that of eosinophil peroxidase, further supports the possibility of two pathways of processing of granule proteins.[26]

Acid phosphatase activity was not visualized in the endoplasmic reticulum or Golgi apparatus of the immature HL-60 eosinophils with either β-glycerophosphate (which stains only lysosomal sites) or p-nitrophenyl phosphate (which stains extralysosomal sites as well).[12] Deposits corresponding to enzyme activity were demonstrated, however, in the Golgi apparatus of other cells which appeared to be differentiating into neutrophils. Thus, the early events in acid phosphatase processing could not be observed in the eosinophils. However, as with peroxidase, the acid phosphatase activity appeared to be included in the flocculent material which condensed to form granules within the vacuoles. Unlike the peroxidase activity, the acid phosphatase activity appeared to be inactivated as it underwent condensation into granules. This type of enzymatic inactivation has been described in normal eosinophils as well.[22] In the granules that underwent crystallization to form multilamellar structures, the acid phosphatase activity appeared to have been inactivated in the areas where the crystallization was well developed but appeared to remain intact where the crystallization was not yet fully formed.

Eosinophilic differentiation of the HL-60 cells was associated with an increase in the total amount of acid phosphatase enzyme activity. Furthermore, the isoenzymes of the acid phosphatase expressed appeared to be similar to those seen in the mature HL-60 neutrophils. Thus, none of the isoenzymes appeared unique for either neutrophilic or eosinophilic differentiation of HL-60 cells.

Arylsulfatase activity and lysophospholipase activity were both detected in the mature HL-60 cells, but at very low levels. In our earlier studies, the presence of lysophospholipase was demonstrated by immunofluorescence techniques with an antiserum prepared against the Charcot-Leyden Crystal protein (identical to lysophospholipase).[9,17] Fluorescence was shown in only a small proportion of cells (maximally 6%), even after induction of differentiation. Therefore, expression of this particular protein is not a constant feature of eosinophilic differentiation of the HL-60 cells, Similarly, arylsulfatase activity was only seen as small deposits on the outside of granules, involving only a minor subpopulation of the cells. Thus, both of these enzymes, which are characteristic of normal eosinophils, appear to be expressed to considerably lower extents in the HL-60 eosinophils.

These data demonstrate several important differences between the HL-60 eosinophils and normal eosinophils. First, both myeloperoxidase and eosinophil peroxidase appear to be coexist in the population of mature HL-60 eosinophils, whereas normal eosinophils have little or no myeloperoxidase. Second, whereas the majority of authors who have examined the role of the Golgi apparatus believe it to be of major importance in the packaging of granule proteins in normal eosinophils, we observed only a variable, minor amount of enzyme activity present in the Golgi apparatus at any time. Third, low levels of arylsulfatase and lysophospholipase activity were demonstrated in the HL-60 cells compared to normal eosinophils and those from patients with secondary eosinophilia. Fourth, in some cells, it was possible to demonstrate structures that have been described as being precursors of Auer rods, whereas these are never seen in normal eosinophils. Taken together, these data suggest that there exists one or more disorders of granule protein synthesis and processing in the HL-60 eosinophils as compared to normal eosinophils. Because of the morphologic and histochemical similarity of the HL-60 eosinophils to those seen in patients with various malignant diseases, especially ANLL-M4eo, we conclude that these disorders of synthesis and processing are very likely responsible, at least in part, for the granular abnormalities seen in the eosinophils of those patients.

ACKNOWLEDGMENT

We thank Margaret Condon, James Watkins, Sonja Beals, and Frederick Howard for technical assistance, Dr Julie Eiseman for valuable technical advice, and Linda Mueller and Yvonne Logan for typing the manuscript.

Long-Term Culture of Bone Marrow-Derived Preleukemic Cells From F-MuLV-Infected Mice

By Jean Michel Heard, Brigitte Sola, Marie-Antoinette Martial, Serge Fichelson, and Sylvie Gisselbrecht

The replication-competent Friend leukemia virus (F-MuLV) induces leukemias involving three hematopoietic lineages after a latent period of several months. In an attempt to elucidate the early events of the leukemogenic process, we looked for a method allowing the isolation and the long term in vitro maintenance of preleukemic cells. When established as long-term cultures according to the technique described by Dexter et al,[1] bone marrow cells obtained from 7/7 apparently healthy F-MuLV-infected preleukemic mice led to the accumulation of immature myeloblastic cells, and to the generation of permanent myeloblastic cell lines, which in most cases further became tumorigenic in preirradiated recipient animals. The delays required to obtain cell lines were shorter when the duration of the in vivo infection was longer, suggesting that these cells were committed into the leukemogenic pathway before their transfer into culture flasks. The myelomonocytic preleukemic cells exhibited normal sensitivity to purified preparations of CSFs, but acquired the capacity to grow in the absence of exogenous CSF stimulation. Examination of integrated provirus copies demonstrated that the preleukemic cell proliferation involved a single or a few clones which may progress in vitro from a preleukemic to a fully malignant stage without major modifications of the integrated provirus copies.

REPLICATION-competent murine leukemia viruses (MuLVs) are retroviruses devoid of oncogenes, that induce leukemias in infected mice after a delay of several months. It is obvious that the crucial events leading to the generation of leukemic cells take place during the latent preleukemic period. In most cases, preleukemic animals are clinically healthy, although anemia and splenomegaly are sometimes observed. A prolonged latent period and the existence of preleukemic myeloproliferative diseases have also been recognized in some human leukemias. This suggests that MuLV-induced long latency leukemias may be useful experimental models for human diseases. However, the understanding of the mechanisms by which MuLV infection leads to leukemias largely depends on the availability of an experimental tool allowing investigations on preleukemic cells.

MuLV-infected preleukemic lymphoid cells were initially detected in mice by Haran-Ghera.[2,3] They were recognized by their ability to induce leukemias of donor origin several months following transplantation into syngeneic recipients. However, all attempts to maintain lymphoid preleukemic cells in cultures have failed in the past.[4] Recently, O'Donnel et al[5,6] isolated preleukemic cells corresponding to successive stages in the development of AKR thymic lymphomas. Attempts to reproduce the preleukemic events were also performed by using the long term culture of murine bone marrow cells described by Dexter et al.[1] Thus, in vitro infection of normal bone marrow cells allowed to follow successive steps in the appearance of Friend virus (FVP)-induced erythroleukemia,[7] and led us to define successive stages in the myelomonocytic leukemic transformation induced by the helper component of FVP, the F-MuLV.[8,9]

F-MuLV-infected mice develop erythroid, lymphoid, and myelomonocytic leukemias after a latency of several months.[10-12] In most mouse strains, the latent period is silent; however, some susceptible strains show a severe anemia with hepatosplenomegaly which is probably not leukemic, and which regresses after blood transfusions.[13] In this paper, we describe the isolation, long-term culture, and in vitro progression toward malignancy of preleukemic cells issued from apparently healthy mice infected as young adults with the I^{-5} strain of F-MuLV.[14] We took advantage of the prevalence of the myelomonocytic progenitor growth and differentiation in the Dexter culture technique[1] to apply it to the long-term culture of the preleukemic myelomonocytic cells supposed to be present within the bone marrow cells of some F-MuLV-infected mice. Indeed, these cultures were progressively overgrown by immature myelomonocytic cells which gave rise to permanent cell lines. This allowed us to isolate preleukemic cells issued from infected animals and to examine their growth factor dependence and the pattern of integrated provirus copies.

MATERIAL AND METHODS

Virus and virus infection. The origin of the I^{-5} stock of F-MuLV has been described previously.[14] Batch used contained 2 × 10^6 focus-inducing units (FIU) per mL in the S^+L^- assay.[15]

Young adult female mice (6 to 8 weeks old) were infected by intraperitoneal injection of 10^5 FIU in a volume of 0.5 mL. For in vitro infection of bone marrow cells, 10^5 FIU in a volume of 1 mL were incubated for 1 hour at 37 °C on monolayer cells. 9 mL of 10% fetal calf serum (FCS) supplemented culture medium were further added into each culture flask.

Cell cultures. Long-term bone marrow cell cultures were established according to the technique reported by Dexter et al,[1] with a few modifications already described.[8,9] Uninfected bone marrow cells were first allowed to grow as an adherent cell layer for 3 weeks. Then, the content of a single femur from either a F-MuLV-infected mouse, or from a normal mouse, was added to the culture. When normal bone marrow cells were infected in vitro, F-MuLV was added simultaneously as described.[7,8] This date was considered as day zero for all the cultures. Cultures were refed twice a week. Once a week, cells collected with the supernatant were used for morphologic examination, for colony assays, and for attempts to establish secondary cultures and cell lines. In the latter case, one half of the culture medium was transferred into a new culture flask at successive intervals of time leading progressively to the elimination of the

adherent cell layer. The same procedure was used to establish cell lines from leukemic animals, except that tumor cells were plated at a concentration of 2 to 5 × 10^5 cells per mL. Established cell lines were maintained as previously described.[8,9]

Cloning assays in agar cultures were performed as described in a previous paper.[16] Purified CSF-1,[17] GM-CSF,[18] and IL-3[19] were kindly provided by Dr Stanley, Dr Burgess, and Dr Ihle, respectively.

Mice, tumor transplantations, and tumorigenicity assays. (C57Bl/6 × BALB/c)F1 mice came from our own breeding and were maintained in pathogen-free conditions. Transplantations of tumors and tumorigenicity assays were performed in 450 rads preirradiated (^{60}Co source) isogenic male adult recipients. Cell-injected animals were regularly observed for the presence of any tumor until 6 months postinoculation. Tumors removed from moribund mice were used for cytologic studies, karyotypic analysis, and tranplantation into secondary recipients. The technique used for karyotypes has been described elsewhere.[8,9]

Detection of integrated F-MuLV genomes. High molecular weight DNA extraction and Southern blots[20] were performed exactly as previously described.[21] Briefly, 10 μg of EcoR1 digested DNAs were run on 0.8% horizontal agarose gels, transferred to nitrocellulose filters, and hybridized in stringent conditions with ^{32}P-labelled nick-translated probe (specific activity, 2 × 10^8 cpm/μg of DNA). Hind III digested lambda DNA was used as size marker.

RESULTS

(C57Bl/6 × BALB/c)F1 hybrids (B6C) have been used since (1) they bear the Fhe allele that confers resistance to the early erythroid disease[22]; (2) they are known to exhibit a long latent period and a high percentage of myelomonocytic leukemias after infection with the I^{-5} isolate of F-MuLV[23]; (3) their bone marrow cells are suitable for the Dexter's culture technique and the in vitro generation of myelomonocytic leukemic cells.[8,9]

Leukemia induction in F-MuLV–infected B6C mice. Twelve young adult B6C mice were infected with the I^{-5} strain of F-MuLV. As expected, none of them exhibited the early erythroid disease. In contrast, 11/12 developed leukemias after a latent period of 45 to 55 weeks, confirming the nearly 100% incidence of leukemias in F-MuLV–infected mice.[23] Determination of the cell lineage origin of the leukemic cells also confirmed the prevalence of the myelomonocytic leukemias (6/11). Bone marrow cells from mice developing myelomonocytic leukemias were used to establish permanent leukemic cell lines in order to compare their growth properties with those of the bone marrow cells issued from apparently healthy preleukemic mice. Figure 1 shows that cells with myeloblastic characteristics (excentred nucleus and myeloperoxidase positive cytoplasmic granules) rapidly grew. Permanent myelomonocytic cell lines were obtained within a few weeks, and were tumorigenic when injected into 450 rads preirradiated syngeneic mice. Tumors exhibited the cytologic characteristics of myeloblastic leukemias.

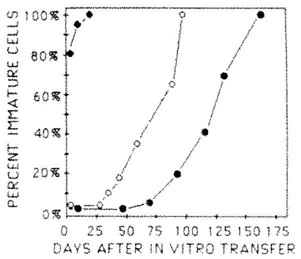

Fig 1. Time course of the percentage of immature cells in newly established leukemic and preleukemic bone marrow cell cultures. ♦: bone marrow cells from an overt F-MuLV–induced myelomonocytic leukemia; ● and ♦: cultures C and P established from bone marrow cells of mice 1 and 5, respectively, 17 and 40 weeks after the F-MuLV infection.

Establishment of myelomonocytic cell lines from preleukemic animals. Seven B6C mice were infected with the I^{-5} F-MuLV and killed during the latent preleukemic period. One mouse was killed at week 17 postinfection, and two mice were killed at weeks 27, 40, and 50, respectively. These animals were carefully examined to check up on the absence of an overt leukemia. Such control was critical for the animals killed at weeks 40 and 50, since the occurrence of leukemias was expected at this time. Mice were considered as healthy when spleen weight and cytologic examination of blood, spleen, lymph nodes, and bone marrow were normal. We also controlled that bone marrow cells formed colonies of fully mature granulocytes and macrophages when plated in agar cultures in the presence of colony stimulating factor (CSF). Bone marrow cells from each mouse were plated in three tissue culture flasks where a feeder layer of normal bone marrow cells had been previously grown (see Materials and Methods) (Fig 2). In the same time, three control uninfected cultures were established from normal B6C mice. Investigations on both preleukemic and normal mouse cultures included twice-a-week examination of the morphology of the nonadherent cell population and attempts to derive secondary cultures in the absence of any exogenous growth stimulating factor.

12/21 preleukemic mouse cultures evolved like uninfected controls. They contained 90% mature granulocytic and macrophagic cells, they were unable to generate secondary cultures, and they ended after 20 weeks (Fig 2).

In contrast, in 9 cultures, after a delay that varied

Fig 2. Experimental schedule and delays needed to isolate preleukemic cells. Mice were picked up randomly within a cage of 20 infected B6C mice from which obviously leukemic animals had been removed. Cultures were established using either 1 femur or 2 tibias. Cultures that did not generate cell line ended between 20 and 30 weeks. *date when the percentage of immature cells reached 50%. §date of the first successful transfer without feeder-adherent cell layer.

according to the culture, the initial fully maturing cell population was substituted by immature cells with excentred nucleus and myeloperoxidase positive cytoplasmic granules. The percentage of immature cells progressively raised 100% (Fig 1). All these cultures were able to generate secondary cultures and later establish cell lines simply by successive transfers of the nonadherent cells into new culture flasks (Fig 2). Neither feeder cell layer nor addition of exogenous growth factor were required. We examined each month the capacity of the cells from primary cultures, secondary cultures, and established cell lines to induce tumors of donor origin when injected into 450 rads preirradiated syngeneic recipient mice. Tumor induction was never observed when cells were inoculated before they could be established as permanent cell line. 6/9 cell lines became tumorigenic. They induced either generalized leukemias or subcutaneous tumors within the inoculation area, or both. The donor origin of tumor cells was controlled by karyotypic analysis, female cell lines being injected into male recipients. Delays for the first engraftment varied from 6 to 12 weeks according to the cell line. Tumors always exhibited the cytologic characteristics of myeloblastic cells. They were transplantable into preirradiated mice and easily adapted to in vitro growth.

Figure 2 shows that 9 cell lines were obtained from 7 F-MuLV–infected mice, and that each sacrificed animal gave rise at least to one permanent cell line. Since no cell line could be derived from uninfected animals, we concluded that the capacity of bone marrow cells to generate permanent cell lines resulted from the F-MuLV infection despite the absence of any clinical expression of the viral infection.

Myelomonocytic cell lines are derived from preleukemic cells present in F-MuLV–infected mice. We have previously shown[8,9] that the in vitro F-MuLV infection of normal bone marrow cell cultures leads to the generation of malignant myeloblastic cell lines in a very similar way to that observed here with preleukemic mouse cultures. Therefore, the question arose of whether the cells originated from infected mice underwent the entire leukemic process after their transfer in vitro, or whether they were already committed into the leukemic pathway at the time of seeding into culture flasks, and could actually be considered as preleukemic cells.

To examine this point, we compared the delays preceding both the increase in the percentage of immature cells and the establishment of permanent cell lines when bone marrow cells were either obtained from infected mice (17, 27, 40, and 50 weeks after the infection), or obtained from uninfected mice and further infected after their in vitro transfer. For this purpose, 8 bone marrow cultures established from normal mice were infected 3 weeks later with the I^{-5} F-MuLV strain. After a period during which infected cultures resembled uninfected controls (12 to 32 weeks according to the culture), the cell production progressively switched toward the generation of immature cells in 5/8 cultures, and cell lines were established a few weeks later.

Figure 3 shows the delays preceding the increase in immature cells (Fig 3A) and the establishment of cell lines (Fig 3B) after both in vivo (black circles) and in vitro (white circles) F-MuLv infection. Data are expressed in terms of the duration of the in vivo infection (this value being zero for in vitro infected cultures, and 17, 27, 40, and 50 for cultures derived from infected animals.) Calculation of the correlation index between delays and duration of the in vivo infection reveals a significant inverse relationship for both the increase of the immature cells (Fig 3A, r = −0.64, $P < 0.02$) and the establishment of permanent cell lines (Fig 3B, r = −0.70, $P < 0.01$). Acceleration of in vivo versus in vitro infected cultures was not due to different levels of virus production since titers of replication-competent MuLVs, as measured by foci induction in S^+L^- cell cultures,[15] were similar in both cases (data not shown). Furthermore, shortening of delays also appeared within the group of the in vivo infected cultures (Fig 1 and Fig 2). A longer period of in vivo infection was related to shorter delays before the increase of immature cells and the establishment of permanent cell lines. These data suggest that in F-MuLV–infected mice some hematopoietic cells had already entered the leukemic pathway at the time of seeding in culture, and thus could proceed toward malignancy more rapidly than normal bone marrow cells infected in vitro.

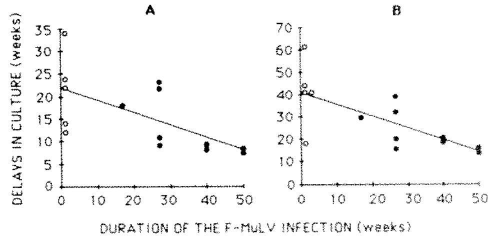

Fig 3. Relationship between the duration of the in vivo F-MuLV infection and the delays needed to isolate preleukemic cells from bone marrow cultures. (A) Delays before the increase of the percentage of immature cells. Plotted points correspond to the date when the percentage of immature cells reached to 50%. (B) Delays before the establishment of permanent cell lines. Plotted points correspond to the date of the first successful transfer without feeder-adherent cell layer. ○: data from bone marrow cell cultures infected in vitro. Duration of the in vivo infection is zero; ●: data from bone marrow cell cultures established from infected mice. Duration of the in vivo infection is 17, 27, 40, or 50 weeks according to the culture. Correlation index had been calculated from each set of individual points according to the formula:

$$r = \frac{\Sigma(x_i - mx)(y_i - my)}{\sqrt{\Sigma(x_i - mx)^2 \Sigma(y_i - my)^2}}$$

where x_i are the duration of the infection in mice, y_i are the delays preceding either the increase of the immature cells or the establishment of permanent cell lines, and mx and my are the algebraic averages of x_i and y_i, respectively. Regression curves were calculated according to the equation $y = my - [(r)(mx)]$.

CSF dependence of early preleukemic myelomonocytic cells. Establishment of permanent cell lines from preleukemic mouse bone marrow cultures was always preceded by two periods: (1) an initial period during which the cultures produced fully maturing cells exactly as did control cultures, (2) an intermediate period characterized by the overgrowth of immature cells while permanent suspension cell lines could not be yet established. We already described such a time course in cultures infected in vitro,[9] and we showed that the intermediate period was characterized by a transient dependence of the cells toward the exogenous stimulation by CSFs.[9]

We examined whether this was also the case in preleukemic cell cultures. For this purpose, nonadherent cells from the culture C were harvested as soon as the percentage of immature cells raised 50%, and were plated in agar cultures in the presence of increasing concentrations of crude and purified preparations of CSFs. Dose-response curves allowed us to estimate the sensitivity of the cells to the various growth-stimulating factors, and to compare it with the one of normal bone marrow cells plated in the same time. Results are shown in Fig 4. No colony was obtained in the absence of stimulating factor. Colony formation was induced by the addition of WEHI-3B–conditioned medium (CM) which is known to contain CSF,[24] and by purified CSF-1,[17] GM-CSF,[18] and IL-3.[19] Sensitivities of the preleukemic cells to CSFs were either similar or lower than those of the normal bone marrow cells. Colonies induced in the presence of CSFs only contained immature myelomonocytic cells. Cells picked up from WEHI-3B CM–induced colonies generated continuous suspension cell lines when transferred in liquid cultures in the presence of the same stimulating factor. Cell morphology remained unchanged even after several weeks of culture in the presence of CSF-containing medium. However, the dependence toward exogenous stimulating factor was lost after 10 weeks. At this time, factor-independent cell lines could be established from the original bone marrow culture, and colony formation could be observed in the absence of added exogenous stimulating factor (data not shown).

We concluded that during a transient period, the early preleukemic myelomonocytic cells remain dependent toward their physiologic growth-stimulating factor (GSF) despite their inability to express the granulomacrophagic differentiation program as do their normal counterparts.

Integrated F-MuLV provirus copies in cultured myelomonocytic preleukemic cells. Clonality of the proliferating tumor cells has been previously demonstrated in murine long latency virus-induced neoplasias.[25,26] The isolation of myelomonocytic preleukemic cells from F-MuLV–infected mice allowed us to examine the cell clonality at the early stages of the leukemic process. For this purpose, we looked at the integrated provirus copies by using an ecotropic virus-specific DNA probe (E57BS) subcloned from the F-MuLV genome.[27] We already used such a procedure to demonstrate that the in vitro leukemic transformation induced by the F-MuLV resulted from a clonal expansion.[21] By Southern blot analysis, the E57BS probe detects a single 3.5 Kb band in the EcoR1 digested DNA of noninfected mouse cells (Fig 5A, lane 1). Analysis of DNA from F-MuLV–induced myelomonocytic leukemic cells showed a limited number of integrated provirus copies (Fig 5A, lane 2) indicating a clonal origin of these cells. DNAs were extracted from the nonadherent cells of bone marrow cultures established from preleukemic F-MuLV–infected mice. When examined before the onset of the immature myelomonocytic cells the E57BS probe detected a smear (Fig 5B, lane 1), showing a random integration of F-MuLV proviruses in these cells, and therefore the polyclonality of the cell population. In contrast, as early as the cultures were overgrown by immature myelomonocytic cells, and before any subcloning of the cell population, discrete numbers of band were detected (Fig 5B, lane 2). Grossly the same hybridization pattern was conserved all along the in vitro proceeding of the cells, and also in the various tumors induced by their in vivo engraftment with the exception that some additional bands and/or deletions have been detected in some cases (Fig 5C, lanes 1, 2, 3). This provided evidence that a small number, or more probably a single preleukemic clone, progressively emerged from the infected cell population sometimes before the increase of the immature cell percentage could be detected.

DISCUSSION

The replication-competent Friend leukemia virus (F-MuLV) is characterized by a multiple hematopoietic tropism involving the lymphoid, the erythroblastic, and the myelomonocytic cell lineages.[10-12] In this paper we show that although apparently healthy, preleukemic F-MuLV–infected B6C mice possess myelomonocytic cells already committed into the leukemic pathway. These cells have been recognized by their capacity to overgrow bone marrow cultures established from preleukemic animals. They consist in a monomorph population of immature cells with myelomonocytic characteristics. They generate permanent autonomous cell lines growing in suspension, and in most cases, become tumorigenic as evidenced by tumor formation in preirradiated recipient mice. Our results also show that the preleukemic cell proliferation is monoclonal, and that the same clone proceeds in vitro from the preleukemic stage until the full malignancy.

In a previous work, we showed that the in vitro F-MuLV infection of normal hematopoietic cells generated malignant myelomonocytic cells.[8,9] Consequently, it might now be objected that the cell lines we derived from F-MuLV–

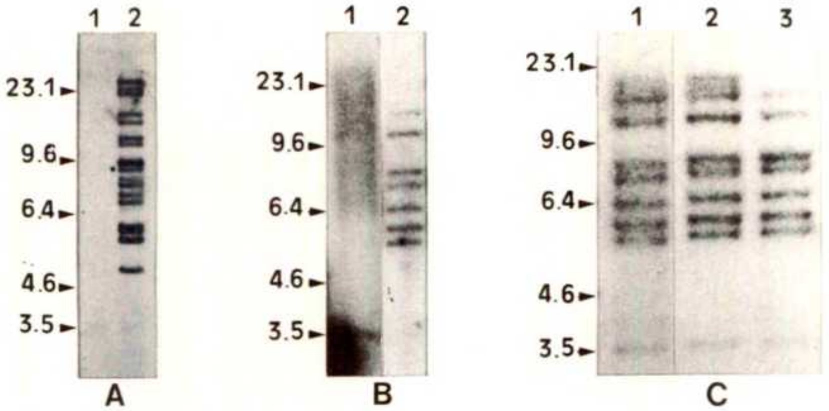

Fig 5. Analysis of integrated F-MuLV provirus copies in preleukemic bone marrow cell cultures. Southern blots of EcoR1-digested DNAs were hybridized with the nick-translated E57BS probe. Panel A: uninfected B6C mouse bone marrow cells (lane 1), cell line established from an overt myelomonocytic leukemia (lane 2); Panel B: P bone marrow culture established from mouse No. 5 killed 40 weeks after F-MuLV infection. Analysis of cells removed before the onset of the immature cells (less than 5% immature cells) (lane 1), and when the percentage of immature cells reached 50% (lane 2). Panel C: cells from the P cell line analyzed when established as a permanent suspension cell line (lane 1), and as tumor cells from two different recipient animals (lanes 2 and 3).

infected mice resulted from hematopoietic progenitors merely infected rather than from truly preleukemic cells. Since preleukemic cells were supposed to need shorter time to reach the leukemic stage than cells infected de novo within the culture flask, we compared the delays preceding transformation when either bone marrow cells infected in vitro or cells from preleukemic mice were used to establish the cultures. We observed that the overgrowth of the cultures by the immature cell population and the generation of permanent cell lines occurred more rapidly when the bone marrow cells came from preleukemic mice. This acceleration was related to the duration of the in vivo infection. It was very unlikely that such an acceleration might result from a higher susceptibility to in vitro virus transformation of old mouse bone marrow cells. Indeed the in vivo susceptibility to virus infection is known to decrease in old animals[29] and if considered in terms of frequency of transformation, the susceptibility of the cultures obtained from old mice was not increased. Furthermore, since the quality of the cultures established from old mice was rather poor, and since high quality cultures are required for in vitro transformation, it is very unlikely that the use of old bone marrow cells improved the efficiency of this leukemogenic process. Therefore we suppose that the shorter delays observed with cells issued from preleukemic mice resulted from their previous commitment into the leukemic pathway.

Surprisingly, we obtained myelomonocytic preleukemic cell cultures from the 7/7 mice that have been killed during the latent preleukemic period. This contrasts with the incidence of the myelomonocytic leukemias in the B6C strain which affects only 50% of the F-MuLV–infected animals. It suggests that myelomonocytic preleukemic cells were present in animals which would later have developed erythroblastic or lymphoid leukemias. This result fits with the known multiple tropism of F-MuLV. It indicates that the initiation of the leukemic process involves several hematopoietic cell lineages within the same animal, and it is consistent with the hypothesis that the F-MuLV target cell would be either the multipotential stem cell or a committed stem cell of each of the various lineages.

We observed that preleukemic cells transiently required a stimulation by exogenous sources of CSFs to form colonies in semisolid agar cultures and to proliferate at low cell density. We previously reported that, in Dexter's bone marrow cultures, CSFs are secreted by the adherent cell layer.[30] It may be assumed that this secretion provides a stimulation that enables the survival and proliferation of the myelomonocytic preleukemic cells, while preleukemic cells from the other hematopoietic lineages are lost in these particular culture conditions. However, although the stimulation by CSFs seems crucial for the isolation of preleukemic myelomonocytic cells, it is probably not responsible for the overgrowth of the cultures by the immature population. Indeed, as shown in Fig 4, preleukemic cells exhibited a sensitivity to CSFs similar to the one observed for uninfected bone marrow cells. This contrasts with data obtained in the erythroid lineage where hyperesponsiveness to traces of erythropoietin had been observed in human polycythemia vera[31] and in murine erythroleukemias induced by the anemia-inducing strain of the Friend virus.[32] We showed elsewhere[16] that during the in vitro myelomonocytic transformation induced by F-MuLV, the same level of sensitivity to CSFs was conserved along the leukemic pathway, and that the existence of an autocrine stimulation of growth did not account for the autonomous cell proliferation.

The monoclonal origin of long latency neoplasias has been previously reported.[25,26] Our analysis of integrated ecotropic provirus copies in the genome of preleukemic and leukemic cells provides evidence that in F-MuLV–infected mice, a monoclonal or oligoclonal population of transformed cells already exists during the latent period. These results are in agreement with recent data from O'Donnell et al[6] who reported the presence of clonal cell populations at the preleukemic stages of the AKR leukemias.

The concept of a preleukemic cell is rather formal and its definition varies according to the authors. Haran-Ghera et al using cells obtained very early after the virus infection, retained as a criterion the development of tumors of donor origin in recipient animals, while delays were similar to those of the virus-induced diseases.[2,3] O'Donnell et al[5] reported that a subpopulation of thymocytes isolated from preleukemic AKR mice 40 to 50 days after MCF virus infection induced accelerated tumor formation in preirradiated recipients. Oliff et al obtained permanent factor-dependent cell lines from mice exhibiting the F-MuLV–induced early erythroid disease (which precedes the occurrence of the leukemias); however, these cells needed the further transfection of the *abl* oncogene to become tumorigenic.[33] No activation of the *abl* oncogene was detected in our cell lines (unpublished data). We obtained evidences that the cell populations we isolated from preleukemic mice were clonal, we showed that the same clone became later tumorigenic, and that in these cells, the progression toward malignancy was shorter than after in vivo or in vitro de novo infection. We assume that these are valuable criteria for the definition of a preleukemic stage, and that our cells may actually be considered preleukemic.

ACKNOWLEDGMENT

We thank Dr R. Stanley, Dr A. Burgess, and Dr J. Ihle who provided us with the purified preparations of CSFs. We also thank Drs J.P. Levy and P. Tambourin for helpful discussions.

Polymorphonuclear Leukocyte Heterogeneity in Neonates and Adults

By Peter J. Krause, Harry L. Malech, James Kristie, Catherine M. Kosciol, Victor C. Herson, Leonard Eisenfeld,
William T. Pastuszak, Alex Kraus, and Bruce Seligmann

We have used a mouse monoclonal antibody (31D8) to determine whether differences in neutrophil (PMN) subpopulations might help explain decreased PMN chemotaxis in neonates compared with that of adults. 31D8 has been shown to bind heterogeneously to adult PMNs. Approximately 80% of the PMNs that strongly bind 31D8 (31D8 "bright") are the same cells that depolarize and migrate chemotactically when stimulated with the chemoattractant N-formyl-methionylleucylphenylalanine, while the 20% that weakly bind 31D8 fail to similarly respond. All neonatal PMNs bound 31D8 heterogeneously. There was a smaller population of 31D8 "bright" cells in neonates at birth (76% ± 6%, n = 45) compared with that of neonates at three to 15 days of age (82% ± 5%, n = 10, $P < 0.002$) and both were smaller than that of adults (88% ± 4%, n = 45, $P < 0.001$ and $P < 0.001$). Neonatal cord PMNs, which traversed a micropore filter in a modified Boyden chemotaxis chamber in the presence of a chemoattractant, had an increased percentage of 31D8 "bright" cells (89% ± 7%) than did PMNs which remained above the filter (82% ± 7%, n = 10, $P = 0.034$). PMN chemotaxis was less in neonates at birth (32.7 ± 4.5 μm) than at three to six days of age (36.8 ± 11.3 μm) and both were decreased compared with that of adults (69.1 ± 12.4 μm, $P < 0.001$ and $P < 0.001$). These findings indicate that decreased PMN chemotaxis in neonates may be due in part to a smaller PMN subpopulation of highly motile cells.

© *1986 by Grune & Stratton, Inc*

THE immature chemotactic function of polymorphonuclear leukocytes (PMNs) in newborn infants is thought to be an important cause of their increased morbidity and mortality due to infection.[1-5] The mechanisms responsible for decreased PMN chemotaxis are not clear although both cellular and humoral abnormalities have been identified.[1-5] Previous studies of PMN chemotaxis in neonates have assumed a homogeneous population of mature cells with heterogeneity of response attributed to less motile immature PMNs. It is clear, however, from studies in adults, that there is a heterogeneous chemotactic response among PMNs that appear mature by light microscopy with approximately 60% to 80% of cells being classified as fast movers.[6-13] It has been shown that one cause of impaired PMN chemotaxis in neonates is an increased percentage of immature PMNs compared with that of adults.[4] The possibility that decreased neonatal PMN chemotaxis might also be due to a smaller percentage of mature, fast moving PMNs in neonates has not been investigated.

Recently, an IgG mouse monoclonal antibody (31D8) has been developed that binds heterogeneously to adult PMNs from the peripheral circulation and to PMN precursors in the bone marrow as early as the myelocyte stage of maturation.[14,15] The antigenic heterogeneity demonstrated by 31D8 binding correlates with PMN functional heterogeneity. Approximately 80% of the PMNs that strongly bind 31D8 (31D8 "bright") are the same cells that depolarize, reduce nitroblue tetrazolium, and migrate chemotactically when stimulated with the chemoattractant N-formyl-methionylleucylphenylalanine (f-met-leu-phe), while the 20% that weakly bind 31D8 (31D8 "dull") fail to similarly respond.[14,15] We studied PMN 31D8 binding and PMN chemotaxis in neonates and adults and noted a significantly smaller percentage of 31D8 "bright" cells and decreased chemotaxis in neonates than in adults. These results suggest that chemotaxis and possibly other functional differences between neonatal and adult PMNs may be explained, at least in part, by differences in PMN subpopulations.

METHODS

Study population. Blood was obtained from the fetal side of placentas (neonatal cord blood) within five minutes of birth, and from healthy, term neonates three to 15 days old. In each case blood was simultaneously drawn from healthy adult volunteers on no medication. Placentas were obtained from healthy women delivered vaginally or by repeat caesarean section who had local anaesthesia, no complications of pregnancy, labor, and delivery, and whose babies were in good health. Blood from older neonates was obtained at the time of heel stick blood sampling for phenylketonuria, a test performed on all newborn infants. All blood samples were immediately mixed with preservative free sodium heparin (50 U/mL blood) and brought to the laboratory for analysis. Informed consent to sample blood was obtained in accordance with the Hartford Hospital Human Investigation Committee guidelines.

Preparation and 31D8 labeling of PMNs. Whole blood was purified using 6% Hetastarch (McGaw Laboratories, Irvine, Calif) that yielded a population of cells composed primarily of PMNs and monocytes as previously described.[16] In some cases the cell population was further purified by Ficoll-hypaque separation yielding a preparation of greater than 90% pure PMNs. Labeling of PMNs with 31D8 antibody was performed as described previously.[14,15] In brief, separated PMNs were washed twice in PBS-BSA, counted, mixed with 31D8 antibody, and allowed to incubate on ice for 45 minutes. The PMNs were then washed three times in PBS-BSA and incubated for 30 minutes on ice with fluorescein isothiocyanate labeled goat-antimouse IgG. The labeled PMNs were washed three more times in PBS-BSA and stored on ice, in the dark, and in the absence of Ca^{2+} or MG^{2+} until use. Separated and labeled cells remained alive as shown by trypan blue exclusion. The following terminology is used in the manuscript for each study group. "adult PMNs" refer to PMNs isolated from the venous blood of adults, "neonatal cord PMNs" refer to PMNs isolated from the cord blood of newborn infants, and "older neonatal PMNs" refer to PMNs isolated from the venous blood of three- to 15-day-old infants.

Analysis by flow cytometry. Flow microfluoremetry was performed using an EPICS C (Coulter, Inc, Hialeah, Fla) with an argon laser emitting 500 mw at 488 n. Forward and 90° light scatter were used to identify the PMN population from lymphocytes and monocytes. The fluorescence intensity distribution of 10,000 PMNs was determined. The data was presented as the number of cells on the vertical axis and log green fluorescence on the horizontal axis divided into a three decade log scale consisting of 255 channels. In some experiments cells were sorted according to fluorescence intensity for further analysis. Gain settings for the photomultiplier tubes for 90° light scatter, forward light scatter, and green fluorescence were gain 5, PMT 400; gain 5; and gain 5, PMT 1300, respectively, and were constant for neonates and adults in all experiments.

PMN locomotory assay. PMN locomotory response was determined using transparent acrylic modified Boyden chambers (Ahlco Corp., Southington, Conn) and nitrocellulose filters (140 μm thick, 5 μm pore size, Nuclepore, Pleasanton, Calif). The assay procedures have been described in detail elsewhere.[16,17] Cells were incubated for one hour with either f-met-leu-phe 10^{-8}_{M} or 3% zymosan activated serum in Medium 199. The results of the nitrocellulose filter assay were assessed using the microsectioning technique which describes the average distance migrated by the cells (locomotion index or LI_{20}).[17] PMNs incubated with the polycarbonate filter were separately harvested from the upper and lower compartments of the Boyden chambers, labeled with 31D8, and analyzed on the flow cytometer.

Statistical analysis. Significance of differences between groups were evaluated using the Student's t test. A P value of less than 0.05 was considered significant.

RESULTS

31D8 binding to adult and neonatal PMNs. The 31D8 antibody bound to neonatal cord PMNs, older neonatal PMNs, and adult PMNs in a heterogeneous manner. The majority of PMNs strongly bound 31D8 (31D8 "bright") and generated a highly fluorescent peak. The remaining PMNs weakly bound 31D8 (31D8 "dull") and generated a contiguous, smaller, less fluorescent area to the left of the major peak. Three typical neonatal cord PMN and adult PMN curves are shown in Fig 1. The 31D8 bright peaks are similar. The 31D8 dull areas are more variable including a distinct peak (1A) or a "shoulder" to the left of the 31D8 bright peak that varies in size (1B–F). PMNs from adults are more concentrated in the bright areas than PMNs from neonates. The adult bright peak in 1D has only a very slight left shoulder and while the other adult curves (1E, F) have larger dull shoulders, they are smaller than those of most neonates. In order to quantitate the size of the bright and dull areas, it was assumed that the 31D8 bright population generated a symmetric curve and that any other cells were part of the dull population.[15] Using the flow cytometer, the area of the entire curve was determined and the area of the symmetric curve about the major peak (bright curve) subtracted from the total area to determine the size of the dull area.

Significant differences in 31D8 antibody binding to neonatal cord PMNs, older neonatal PMNs, and adult PMNs were noted with this analysis as shown in Table 1. Neonates at birth had a smaller population of 31D8 bright cells (76% ± 6%) than neonates three to 15 days of age (82 ± 5%, $P < 0.01$), and both had a smaller population of 31D8 bright cells compared with that of adults (88% ± 4%, $P < 0.001$, and $P < 0.001$). The mean skew and kurtosis of the curves

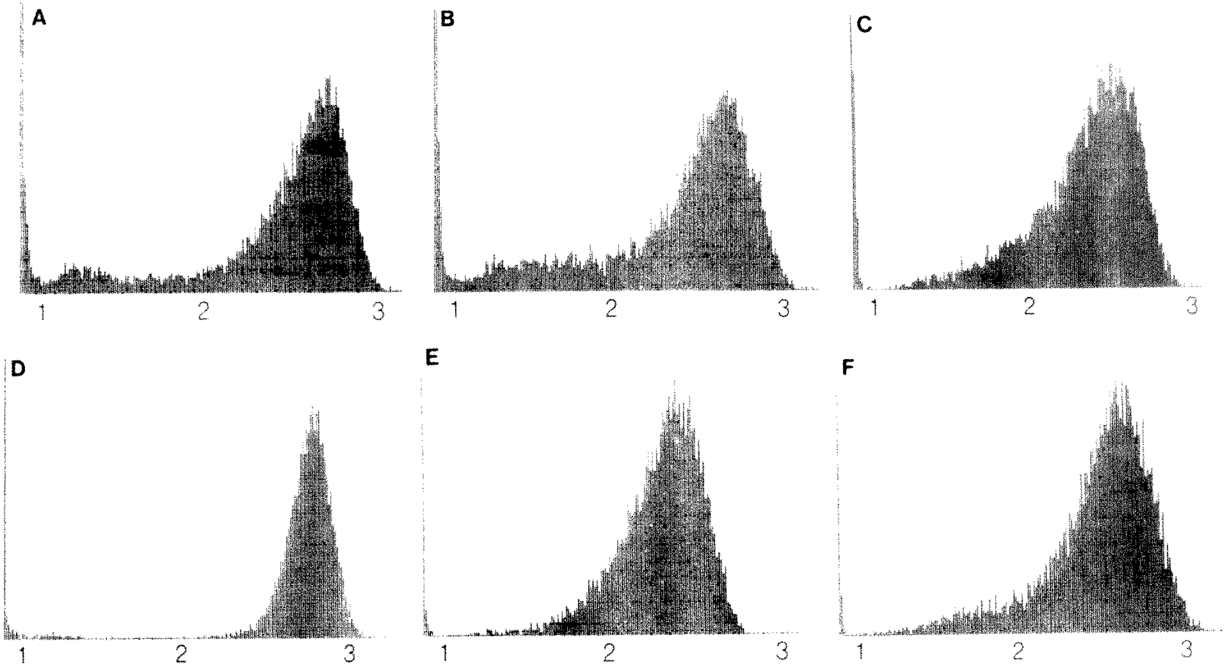

Fig 1. 31D8 antibody binds PMNs heterogeneously. The illustrations are representative curves of 31D8 antibody binding to PMNs in neonates (1A–C) and adults (1D–F). In 1A there is a major peak consisting of 31D8 bright PMNs and a minor peak of 31D8 dull PMNs. In 1D-F there is a single major peak of 31D8 bright PMNs with a "shoulder" or "tail" to the left of the major peak consisting of 31D8 dull PMNs. The horizontal axis depicts fluorescence intensity with cells to the left of 1 exhibiting autofluorescence, 1–2 one log fluorescence, and 2–3 two log fluorescence. The vertical axis depicts the number of PMNs. The percentage of 31D8 bright cells are as follows: 1A: 65%, 1B: 69%, 1C: 77%, 1D: 91%, 1E: 87%, 1F: 86%.

Table 1. 31D8 Monoclonal Antibody Binding to Adult and Neonatal PMNs

		Mean Fluorescent Antibody Distribution Characteristics		
Subjects	n	31D8 Bright Cells (%)	Skew	Kurtosis
Adults	45	88 ± 4 (a)	−1.8 ± 0.8 (d)	11.5 ± 4 (g)
Neonates (3 to 15 days old)	10	82 ± 5 (b)	−1.8 ± 0.5 (e)	7.2 ± 2 (h)
Neonates (Birth)	45	76 ± 6 (c)	−1.4 ± 0.5 (f)	5.8 ± 2 (i)

Significant differences ($P < 0.01$) were noted among the groups in each column except for (h) *v* (i), $P < 0.05$, and (d) *v* (e), $P = 0.8$.

were also determined as another method to compare neonatal and adult 31D8 binding. The neonatal fluorescence curves had a decreased mean skew and kurtosis compared with those of adults (Table 1). There was no significant difference in 31D8 bright populations in females or males in adults (89% ± 3%, and 88% ± 4%, respectively), neonates at birth (77% ± 5%, and 75% ± 6%, respectively), or neonates three to 15 days of age (84% ± 3% and 81% ± 5%, respectively).

Differences in 31D8 fluorescence intensity between adult PMNs, neonatal cord PMNs, and older neonatal PMNs were not due to cell size, as determined by comparing forward light scatter on the flow cytometer for the 31D8 bright and dull subpopulations in the three groups. There was also no difference in the location of antibody binding to neonatal cord PMNs, older neonatal PMNs, and adult PMNs. In all cases there was uniform distribution of fluorescently tagged 31D8 around the periphery of the PMNs. PMN activation with f-met-leu-phe for 60 minutes at 37 °C did not affect the bright/dull cell ratio. There was no difference in the percentage of bright cells in PMNs incubated in Medium 199 or f-met-leu-phe from four neonates at birth (79% ± 5% and 81% ± 6%, respectively) or from four adults (90% ± 3% and 89% ± 4%, respectively).

Because of the possibility that the differences observed in 31D8 binding between neonates and adults were due to an increased percentage of immature PMNs (bands and metamyelocytes) in neonates, we labeled PMNs from three neonates (cord blood) and three adults with 31D8, sorted them into 31D8 bright and dull subpopulations, and analyzed the subpopulations for percentage of mature and immature PMNs. There was no signficant difference in the percentage of immature PMNs in 31D8 bright and dull subpopulations for neonates (16% ± 3%, and 21% ± 11%, respectively), adults (13% ± 7% and 17% ± 11%, respectively), or the total group of neonates and adults (15% ± 5% and 19% ± 10%, respectively).

Correlation of 31D8 binding and PMN chemotaxis. Neonatal cord PMNs from four individuals were incubated in Boyden chambers, collected above and below polycarbonate filters after migration in response to 3% zymosan activated serum, and labeled with 31D8. PMNs that traversed the filter had a log greater mean fluorescence intensity than PMNs that remained above the filter (Fig 2). PMNs that traversed the filter also had a higher mean percentage of 31D8 bright cells (89% ± 7%) than PMNs that remained above the filter (82% ± 7%, $P = 0.034$). These observations indicate that a motile PMN subpopulation in neonates expresses a larger amount of 31D8 antigen on its surface than a less motile subpopulation of cells.

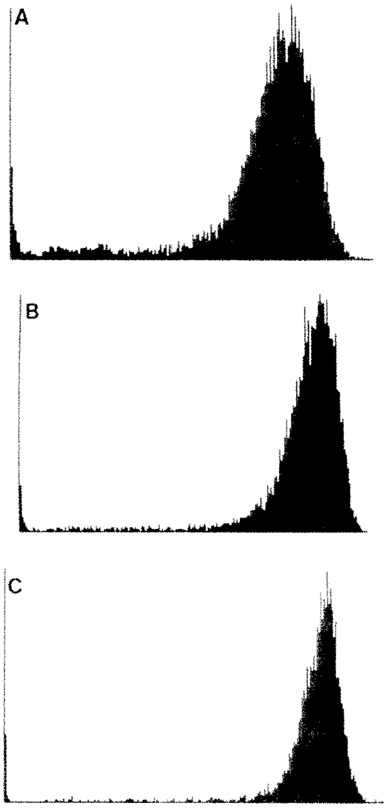

Fig 2. A motile subset of PMNs have a higher 31D8 fluorescence intensity than the total PMN population. In a representative experiment, PMN aliquots were labeled with 31D8 directly (A) and after one hour incubation in a Boyden chamber at 37 °C with 10_{M}^{-8} fmlp in the lower chamber (B, C). PMNs were collected from above the micropore filter (B) and below the micropore filter (C). The horizontal axis depicts fluorescence intensity using the same scale as in Fig 1. The vertical axis depicts the number of PMNs.

The difference in 31D8 expression in the "fast" PMNs that traversed the filter and "slow" PMNs that did not traverse the filter was not due to cell activation during passage through the filter since the percentage of bright cells was not affected by preincubation with f-met-leu-phe as mentioned previously. Furthermore, studies of Seligmann et al[15] showed that when PMNs are prelabeled with 31D8 and placed in the Boyden chamber, the population of cells that traverse the micropore filter into the bottom chamber have a higher percentage of 31D8 bright cells than those that remain in the upper compartment. This data shows that possible alteration in 31D8 expression by contact with the filter or exposure to greater concentrations of f-met-leu-phe does not account for differences in 31D8 expression between the "fast" and "slow" PMNs.

PMN chemotaxis using f-met-leu-phe and 31D8 antibody binding were simultaneously tested in five neonates at birth and adults. The mean chemotactic and 31D8 binding values for neonates were 28.8 ± 4.6 µm and 76.8% ± 6.2%, respectively, and for adults 52.7 ± 9.7 μm, ($P < 0.001$) and 88.8% ± 3.9%, $P < 0.001$), respectively. PMN chemotaxis using 3% zymosan activated normal serum was studied in six other neonates at birth and again at three to six days of age and in 12 healthy adults. Mean chemotactic (LI_{20}) values were 32.7 ± 4.5 μm, 36.8 ± 11.3 μm, and 69.1 ± 12.4 μm ($P < 0.001$ and $P < 0.001$, respectively). Thus, the magnitude of both the PMN chemotactic response and 31D8 antibody binding were smallest in neonates at birth, increased in neonates three to 15 days of age, and greatest in adults.

DISCUSSION

The results of this study demonstrate a clear difference in 31D8 monoclonal antibody binding to PMNs between neonates and adults. There was heterogeneous binding to PMNs of both groups, but neonates had a smaller percentage of cells that strongly bound 31D8 (31D8 bright) compared with that of adults. The percentage of 31D8 bright cells in neonates three to 15 days of age was intermediate between that of neonates at birth and adults. Several possible explanations for these differences were examined. The location of antibody binding sites on PMNs from neonates and adults was similar with uniform distribution of fluorescently tagged 31D8 antibody over the cell surface. There was also no difference in cell size of the 31D8 bright and dull subpopulations in neonates and adults as demonstrated by similar forward light scatter on the flow cytometer. There were no differences in eosinophil counts between neonates and adults. A higher eosinophil count in neonates could have accounted for the difference in 31D8 antibody binding since eosinophils weakly bind 31D8. Finally, although there was a greater percentage of immature PMNs (bands and metamyelocytes) in neonates than in adults, immature PMNs were equally distributed in the 31D8 bright and dull subpopulations. It is possible that 31D8 dull cells are less differentiated than 31D8 bright cells and that light microscopy is not sensitive enough to detect subtle PMN maturational changes.[6] This is unlikely, however, because 31D8 expression is not a late maturational event in PMN development but appears at the level of the myelocyte or metamyelocyte in the bone marrow.[15] Furthermore, a recent study by Gallin et al of 31D8 antibody binding to PMNs of patients with chronic myelogeneous leukemia suggests that 31D8 bright or dull cells may reflect true PMN subpopulations that originate from distinct stem cells.[18]

The cause for the difference in 31D8 binding in healthy neonates and adults is unclear. Since 31D8 binding is not affected by cell activation, changes in 31D8 binding must be due to increased production or destruction of 31D8 subpopulations. It is probably not due to differences in circulating estrogens or progesterone since unpublished observations by us of 31D8 PMN binding in seven pregnant women showed no difference in 31D8 binding during pregnancy and postpartum compared with nonpregnant control subjects. Neonates have a marked neutrophilia at birth that persists for 48 to 72 hours. Recent studies in neonatal rats indicate that the size, number of cell divisions, and rate of production of PMNs is different in neonates than in adults.[19,20] These differences might account for PMN 31D8 subpopulation differences between neonates and adults.

The PMN antigenic heterogeneity detected by 31D8 antibody binding correlates with functional heterogeneity and may help explain observed functional differences between neonates and adults. Neonatal cord PMNs that traversed polycarbonate micropore filters into the lower compartment of Boyden chambers expressed a greater amount of 31D8 antigen on their surface and had a higher percentage of bright cells compared with PMNs that remained above the filters. Seligmann et al also found that PMNs that traversed micropore filters had a significantly higher percentage of 31D8 bright cells when the cells were labeled with 31D8 before placement in the Boyden chambers.[15] This indicated that up-regulation of 31D8 antigen was not a sufficient explanation for the increased percentage of 31D8 bright cells among the PMNs that traversed the micropore filter. Furthermore, we noted a progressive increase in PMN chemotaxis and 31D8 antibody binding in neonates studied at birth, again at three to 15 days of age and in adults. Although there is insufficient evidence to determine the quantitative contribution of 31D8 subpopulation changes to alterations in chemotactic responses, these results suggest that decreased PMN chemotaxis in neonates may be due in some part to the smaller percentage of highly motile 31D8 bright PMNs found in neonates compared with that of adults.

Chromosomal Translocations Play a Unique Role in Influencing Prognosis in Childhood Acute Lymphoblastic Leukemia

By Dorothy L. Williams, Jerry Harber, Sharon B. Murphy, A. Thomas Look, David K. Kalwinsky,
Gaston Rivera, Susan L. Melvin, Sanford Stass, and Gary V. Dahl

Certain types of chromosomal abnormalities have been shown to exert strong independent influence on treatment outcome in acute lymphoblastic leukemia (ALL). To identify the changes most closely associated with prognosis, we analyzed the completely banded blast cell karyotypes of 161 children with this disease. One hundred twenty-five cases had one or more chromosomal abnormalities, with 45 showing translocations. The frequency of translocations was highest (58%) among patients with pseudodiploid karyotypes and lowest (0%) in the hyperdiploid group defined by 51 or more chromosomes. During the maximum 6-year follow-up period, 30 of the 45 patients with a translocation failed therapy, compared with only 27 of the 116 who lacked this feature. Life-table estimates of event-free survival indicate that only 14% of the translocation group will be in complete remission at 3 years. The percentages of failures associated with random and non-random translocations were virtually identical (68% v 65%). When entered in a Cox proportional hazards model with seven other types of chromosomal abnormalities, and then with 11 clinical and laboratory variables of known prognostic value in ALL, translocation emerged as the strongest single predictor of treatment outcome ($P < 0.0001$). The model indicated that translocation increases the risk of treatment failure six times by comparison with the absence of this feature. These findings offer an explanation for the majority of early treatment failures in childhood ALL, including those previously attributed to ploidy classification.

IDEALLY, prognostic factors should allow unequivocal separation of risk groups at diagnosis so that more effective treatment can be devised for patients likely to fail. Acute lymphoblastic leukemia (ALL) is now curable in more than 50% of children,[1,2] making it possible to concentrate on achieving an optimal risk:benefit ratio for modern therapy. Past reliance on clinical, cytologic, and immunologic factors to classify newly diagnosed patients with ALL has led to relatively diverse systems for assignment of risk categories.[3] Sharpening the focus of patient selection methods would be advantageous as a means of improving the reliability, efficiency, and interpretability of clinical trials.

Chromosomal abnormalities have attracted much recent attention as important prognostic factors in ALL. Secker-Walker et al[4,5] were the first to demonstrate that chromosome number (or ploidy) strongly influences treatment outcome in childhood leukemia patients, a relationship that has subsequently been confirmed by others.[6-8] Among 136 children with ALL, we found that those with modal chromosome numbers of 51 or above had the most favorable treatment responses, whereas those with pseudodiploid karyotypes had the poorest responses.[7] Patients with apparently normal, hypodiploid, or 47–49 chromosomes had intermediate responses. The data generated at the Third International Workshop on Chromosomes in Leukemia,[6] comprising 330 children and adults with ALL, showed that the specific karyotypic patterns provided significant independent prognostic information, both with regard to remission duration and to survival. Bloomfield et al[9] have published data indicating that chromosomal translocations, in general, have an adverse effect on prognosis in ALL.

To assess the impact of leukemia cell karyotype and its component parts on disease-free survival, we analyzed an array of chromosomal and other presenting clinical and laboratory features for 161 children with ALL who had complete G-banding of all chromosomes and adequate follow-up. The results demonstrate that the presence or absence of a translocation conveys the most clinically useful information of all prognostic features examined.

MATERIALS AND METHODS

Patients and Treatment

Of 398 consecutive patients with newly diagnosed ALL admitted to St. Jude Children's Research Hospital from July 1, 1978, to January 1, 1983, 301 had adequate bone marrow samples and successful chromosome studies; 161 of these cases had complete G-banding of all chromosomes. The present analysis was restricted to the latter group to avoid possible underrepresentation of clonal abnormalities. The 161 patients were entered in three institutional clinical trials: 17 in Total Therapy Study IX and 137 in Study X (95 in the standard-risk arm and 42 in the high-risk arm),[7] 7 of the 8 B-cell ALL patients were treated separately (unpublished results, protocol available on request). Although treatment components differed among the three studies and between subdivisions of Study X,[7] times to failure for patients with fully banded chromosomes showed no significant differences by major therapeutic protocol ($P = 0.164$, data not shown); similarly, the clinical features and times to failure for all censored patients ($n = 237$) were comparable to those of the 161 patients in the study group. All patients were enrolled in studies (that included a cell profile analysis) approved by the institution's clinical trials committee. All patients were advised of the procedures and attendant risks, in accordance with institutional guidelines, and informed consent was obtained in each instance.

The percentage of completely banded cases versus the total number of patients admitted to the hospital per year is as follows: 20% (8/41) in 1978, 27% (24/88) in 1979, 34% (30/88) in 1980, 46% (46/100) in 1981, and 58% (53/92) in 1982. These percentages

do not include cases with partial banding or those in which only ploidy classification was obtained.

The distribution of follow-up times for patients with complete banding was as follows: 22 cases for 0 to 2 years, 51 cases for 2 to 3 years, 40 cases for 3 to 4 years, 27 cases for 4 to 5 years, and 21 cases for 5 to 6 years. Follow-up time was defined as the number of years between the date on-study and the analysis date (ie, August 1, 1984).

Chromosome Analysis

Chromosomes were prepared by a direct bone marrow technique for ALL developed in our laboratory.[10] Marrow cells were collected in RPMI-1640 medium supplemented with 30% fetal calf serum. Only 0.1 mL of sedimented cells was processed per centrifuge tube. Without delay, the cells were exposed to Colcemid (0.06 μg/mL) for 25 minutes, and then to hypotonic KCL (0.075 mol/L) for a total of 32 minutes (including mixing time, standing time, and centrifuging time). They were then fixed in 3:1 methanol-acetic acid (v/v) and slides were prepared by an edging-flaming technique. Appropriate drying of the slides was achieved by natural aging. G-banding was done by treatment with trypsin and staining with Wright's stain.

For each case, 10–35 metaphases (mean, 20) were studied by direct microscopy to determine the modal number and to identify the malignant stem-line. Karyotypes were prepared from photographic prints. Chromosomal abnormalities were classified according to international conventions.[11,12] The definition of an abnormal stem line was that proposed by the Second International Workshop on Chromosomes in Leukemia.[13] A case was considered abnormal if it had an abnormal clone, regardless of the proportion of normal metaphases. In 12 of 13 cases with two leukemic lines, the second line derived from the other through clonal evolution; hence, only the primary line was included in this study. For the single case with two independent stem lines, both lines were included. Because some chromosomal abnormalities appeared in only one to three cases, they were not included in the statistical analysis. These included rings, inversions, and tiny DNA fragments; because all of these occurred in cases with multiple abnormalities, no individual case was excluded.

The abnormalities analyzed were whole chromosome gain or loss, translocation, unidentified DNA addition not included in translocation because a duplication could not be ruled out, DNA loss (deletion) not identified in a translocation, DNA duplication, isochromosome, and unidentified marker. Translocations were designated as "random" or "nonrandom." The random translocations were those appearing only once, and to our knowledge, not previously reported at the time of this study. The nonrandom translocations were those that appeared two or more times and/or have been reported to cluster.

Hematologic and Immunophenotypic Studies

The diagnosis of ALL was based on morphologic criteria of the French-American-British (FAB) group[14] and negative myeloid-associated cytochemical findings.[15] Immunophenotypes, determined by published methods,[16–21] supported the diagnosis in all instances.

Statistical Analysis

Time-to-failure curves were plotted by the method of Kaplan and Meier,[22] and significant differences were determined with the Mantel-Cox statistic.[23] Failure was defined as a lack of response to induction therapy, a relapse during first complete remission, or death due to any cause. Cox regression analysis[24] was used to assess the influence of chromosomal abnormalities and other potentially important prognostic factors on failure rate. This "proportional-hazards" model permits measurement of the contribution of a given covariate to duration of complete remission while simultaneously adjusting for the contributions of other covariates. The prognostic factors studied, in addition to chromosome abnormalities and chromosome number, were log leukocyte count, relapse risk as defined for Total Study X at St. Jude Hospital, mediastinal mass, age, sex, race, cell markers, FAB type, E-rosette formation, and CNS leukemia.

RESULTS

Modal Number of Chromosomes

The distribution of chromosome numbers was typically bimodal,[7] with the first peak occurring at 46 chromosomes (representing mainly patients with pseudodiploid karyotypes) and the second at 55 chromosomes (Fig 1). Each ploidy group appeared to be adequately represented by comparison with findings from an earlier analysis of 136 cases including both partially and fully banded karyotypes.[7] Although the percentage of cases containing a normal karyotype (22%) is not typical of our more recent studies (6%), this group was included in order to obtain the proper perspective in regard to prognosis.

Chromosomal Abnormalities By Ploidy Group

Overall, the most frequent chromosomal abnormalities by case distribution were whole chromosome additions (62 cases), translocations (45 cases), unidentified markers (34 cases), whole chromosome loss (32 cases), and DNA deletions (28 cases). Because of the established relationship between modal chromosome number and prognosis,[4–8] we next determined the distribution of chromosomal changes according to ploidy group. The results (Fig 2) depict structural and numerical differences as well as specific chromosomes involved in translocations. Findings for the hypodiploid group, which comprised only nine cases, did not permit valid conclusions and were omitted from the figure.

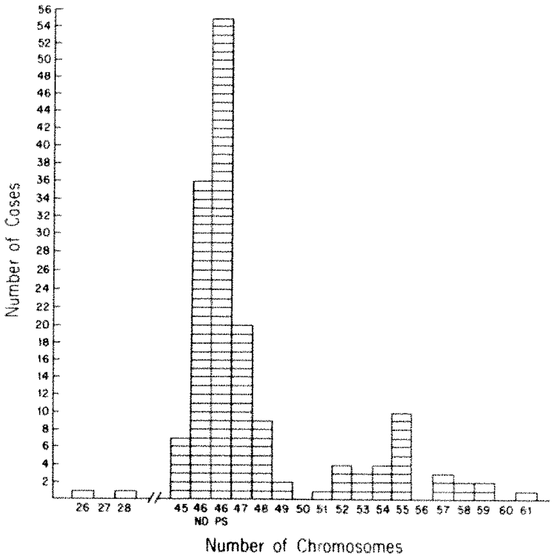

Fig 1. Distribution of modal numbers among 161 cases of childhood ALL. Note the bimodal distribution pattern, with the first peak occurring at 46 chromosomes (pseudodiploid) and the second at 55 chromosomes. ND = normal diploid; PS = pseudodiploid.

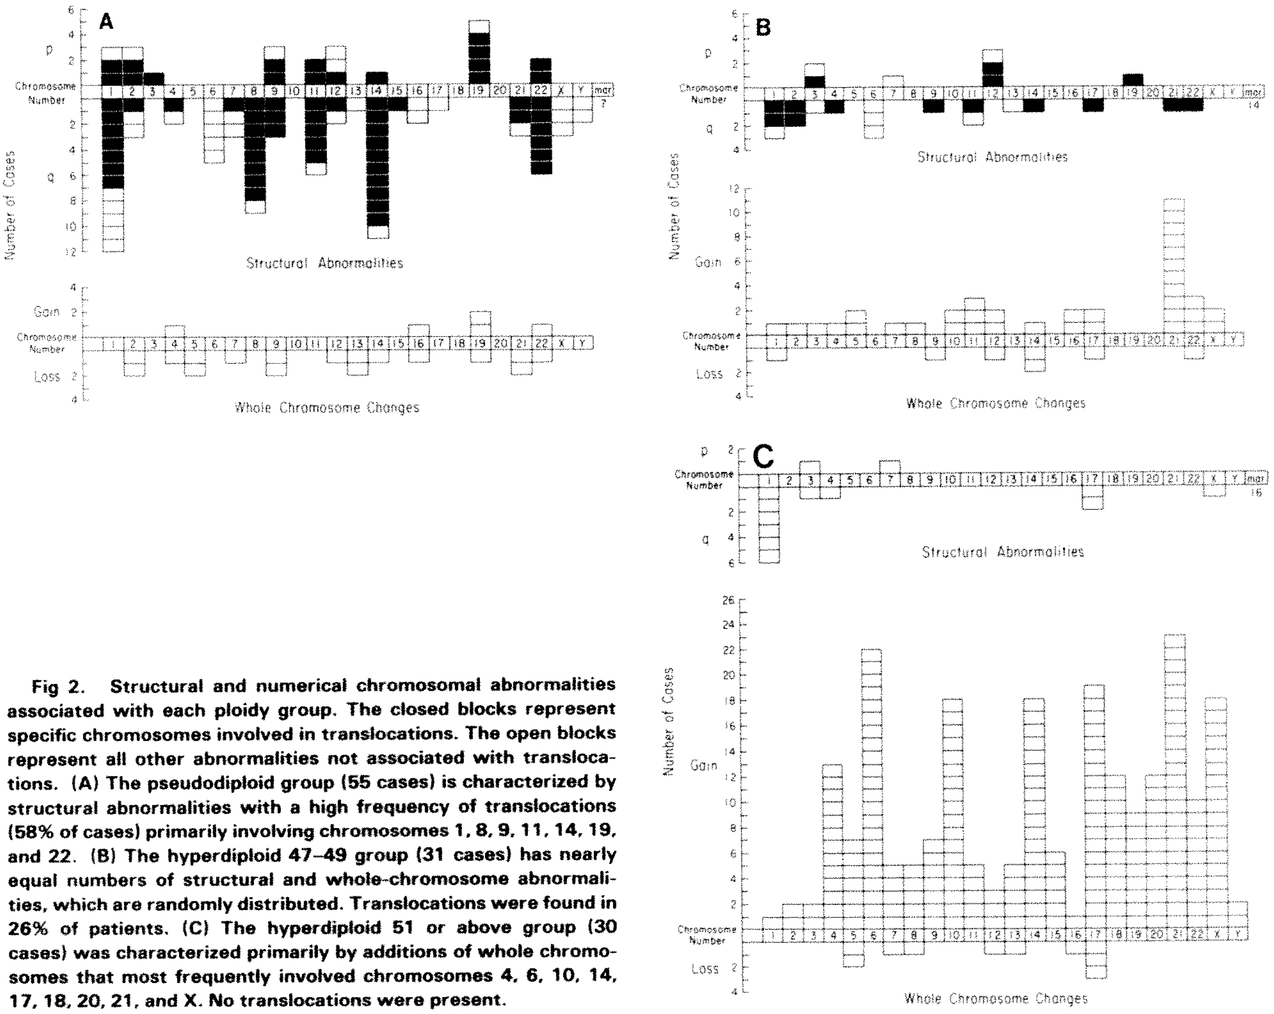

Fig 2. Structural and numerical chromosomal abnormalities associated with each ploidy group. The closed blocks represent specific chromosomes involved in translocations. The open blocks represent all other abnormalities not associated with translocations. (A) The pseudodiploid group (55 cases) is characterized by structural abnormalities with a high frequency of translocations (58% of cases) primarily involving chromosomes 1, 8, 9, 11, 14, 19, and 22. (B) The hyperdiploid 47–49 group (31 cases) has nearly equal numbers of structural and whole-chromosome abnormalities, which are randomly distributed. Translocations were found in 26% of patients. (C) The hyperdiploid 51 or above group (30 cases) was characterized primarily by additions of whole chromosomes that most frequently involved chromosomes 4, 6, 10, 14, 17, 18, 20, 21, and X. No translocations were present.

Briefly, this group contained two near-haploid cases (with 26 and 28 chromosomes) and seven cases with 45 chromosomes containing different karyotypes. Five of the latter cases contained translocations (two nonrandom and three random). Each of the nonrandom translocations was identified as the t(1;19) abnormality specifically associated with pre-B–cell ALL.[25-28]

Pseudodiploid group. All but one of these 55 cases contained structural abnormalities most frequently involving the long arms (q) of chromosomes 1, 8, 11, 14, and 22 (Fig 2A). Translocations were observed in 32 cases (58%). Twenty nonrandom translocations were identified: seven containing the t(8;14) or $14q^+$ abnormality, all with B-cell ALL; six the t(9;22) or $22q^-$; one the t(4;11); four the t(1;19), all with pre-B–cell ALL; and two the t(11;14), both with E^+ T-cell ALL.[25] Twelve different, apparently random translocations were observed. Structural abnormalities not involving translocations were found in 41 other chromosomes, and there were seven banded but unidentified markers. Numerical changes were much less frequent than structural abnormalities and all were random.

Hyperdiploid group, 47–49. In these 31 cases, numerical and structural abnormalities were distributed nearly equally (Fig 2B). The distribution of abnormal chromosomes was random, and when the six cases of Down's syndrome with trisomy 21 were excluded, the frequency of an added chromosome 21 (5 cases) was insignificant. Translocations occurred in eight cases (26%), and included three nonrandom [t(9;22), t(1;19), and t(4;11)] and five random translocations. Comparison of karyotypes containing 47, 48, and 49 chromosomes failed to disclose any related patterns of abnormalities, and there were no similarities between this ploidy group and the group with 51 or more chromosomes (see below).

Hyperdiploid group, 51 or above. This group of 30 cases differed markedly from the other abnormal ploidy groups, with most of the abnormalities involving whole chromosome additions (Fig 2C). Extra chromosomes formed trisomies, with numbers 4, 6, 10, 14, 17, 18, 20, 21, and X added most frequently and number 21 added twice in 12 cases. This apparent nonrandom addition of at least nine chromosomes contributed to the secondary peak of 55 chromosomes apparent in Fig 1. Only one patient in this group had Down's syndrome with trisomy 21, and the leukemic clone contained only that one extra 21 chromosome. Thus, the influence of cases with Down's syndrome on the observations related to chromosome 21 was negligible. Structural abnormalities were relatively infrequent, most often involving 1q in a partial duplication, and included 16 unidentified markers. Translocations were not identified in these 30 cases.

Our most recent studies indicate that translocations do occur in this group, in up to 14% of cases, but this number is still relatively small in comparison to the other ploidy groups. Preliminary results indicate that as in other ploidy groups, the presence of a translocation carries more prognostic import in this setting than does hyperdiploidy. Additional case studies and longer follow-up are needed to confirm this finding.

Treatment Response According to Chromosomal Abnormality

From the preceding analysis, it was clear that a high frequency of structural abnormalities, particularly translocations, distinguishes pseudodiploid cases. This was in contrast to the high frequency of added intact chromosomes and the relative paucity of structural abnormalities, including translocations, in the 51 or above group. Table 1 tests our impression that the presence or absence of a translocation explains prognostic differences among commonly recognized ploidy groups. Within the pseudodiploid and 47–49 groups, the presence of a translocation had a highly significant influence on the frequency of treatment failure. In the pseudodiploid group, only 56% of patients with a translocation achieved a complete remission (CR). The best overall response was found in the group with 51 or more chromosomes, which contained no translocations. When the analysis included only cases without translocations, failure rates among the three ploidy groups showed no significant differences ($P = 0.4246$). Addition of hypodiploid cases without translocations, as well as cases with normal karyotypes, did not alter this finding ($P = 0.8050$, data not shown).

Overall, patients with translocations had strikingly different times to failure compared with those lacking the abnormality ($P < 0.0001$, Fig 3A). Remission induction failure rates also differed: 20% for the translocation group versus 4% for others ($P = 0.002$). All but 1 of the 30 patients with translocations who failed did so within 2½ years, while receiving combination chemotherapy; whereas those without translocations had a more variable clinical course. A comparison of survival times (Fig 3B) emphasized the aggressiveness of disease in cases with translocations. Only two patients

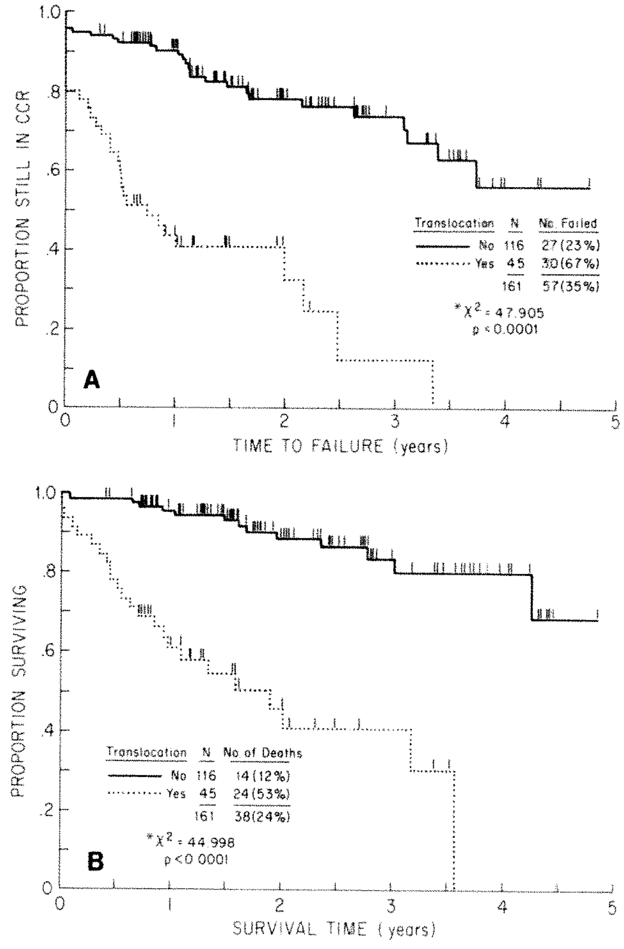

Fig 3. Time to failure (A) and survival time (B) by presence or absence of a translocation. The Kaplan-Meier curves in panel A depict differences in times to failure for the translocation and nontranslocation groups. Remission induction rates differ as indicated by the starting points on the graph at time 0. Nearly all patients with translocations who failed did so by 2½ years or before the end of therapy, whereas in the nontranslocation group the failure pattern is more variable. A similar pattern appears in the analysis of survival times (panel B), indicating the agressiveness of the disease in the translocation group. Of patients with translocations who died, 92% (22 of 24) died before 2½ years.

†Failures.

in this category have lived beyond 3 years from diagnosis despite attempts to secure new remissions.

Table 2 lists all of the translocations identified in the study, categorized as either nonrandom or random. The first group consisted of well-recognized translocations identified in 26 patients; the second comprised 20 different translocations (not previously found in clusters) in 19 patients and involved many different chromosomes. Comparison of failure rates over time, using the Mantel-Cox statistic, disclosed no significant differences between the two groups (P = 0.9078, data not shown).

Multivariate Analysis

Table 3 shows the relative prognostic importance of the eight major categories of chromosome abnormalities, as determined by Cox regression analysis. When the categories were studied singly, translocation exerted the strongest influence on remission duration ($P < 0.0001$), followed in descending order by whole chromosome gain ($P = 0.0165$) and unidentified marker ($P = 0.0578$). After adjustment for translocation, neither variable retained significance, but translocation lost none of its predictive power in the presence of other covariates.

A number of clinical and laboratory features have been found in the past to have prognostic value in childhood ALL.[1] Prominent among these have been leukocyte count, mediastinal mass, age, sex, race, immunophenotype, FAB type, and CNS leukemia. Table 4 lists the distribution of these features among our population of patients separated as: (1) those without a translocation and (2) those with a translocation. In those with a translocation there is a higher frequency of increased leukocyte counts, black race, B-cell phenotype, L3 FAB type, and CNS leukemia. When the eight features were studied in each of the 45 patients with a translocation individually, results indicated that 37 out of 45 (82%) had at least one high-risk feature.

Since the majority of patients with a translocation had one or more "classic" high-risk features, it was important to account for their competing effects on treatment outcome. Thus, the same proportional hazards model was used to determine the influence of translocation on failure rates relative to these well-recognized prognostic factors in ALL (Table 5). In the univariate analysis, translocation, and ploidy emerged as the strongest variables ($P < 0.0001$). Log leukocyte count ($P = 0.0021$) also made a significant contribution, as did cell markers ($P = 0.0378$). When the individual variables were adjusted by translocation, only chromosome number retained significance but at a greatly reduced level. Again, as in Table 3, no covariate added prognostic information to translocation, even when the four next most important factors (log leukocyte count, chromo-

some number, relapse risk, and cell markers) were considered as a group (data not shown).

From results of the Cox regression analysis, it was possible to calculate the relative risk of treatment failure associated with each covariate. Patients with a translocation were six times more likely to fail treatment than those without the abnormality. The probability of treatment failure before the end of the first year was much greater for patients with translocations: 0.57 *v* 0.10 for patients lacking the abnormality. Similarly, those with translocations had a much greater probability of dying (0.39 *v* 0.05).

DISCUSSION

In this analysis of fully banded chromosomes from a large series of childhood leukemia patients, we were able to identify translocation as the abnormality most frequently associated with treatment failure. These observations confirm and extend some of the work of the Third International Workshop[6] and of Bloomfield et al.[9] The unusual distribution of translocations, predominantly among the pseudodiploid group, offers an explanation for the prognostic strength assigned to chromosome number in previous studies.[4-8] The relatively small number of translocations in the 51 or above group, first observed by the Third International Workshop on Chromosomes in Leukemia,[6] is consistent with the low failure rate observed in this study (Table 1) and the paucity of other high-risk features previously observed among patients in this category.[7] Moreover, these hyperdiploid ALL cases had an apparent nonrandom pattern of whole chromosome additions, forming trisomies, that was not seen in the 47–49 or other ploidy groups; cases with exactly 50 chromosomes have not been observed by us at diagnosis. These facts provide compelling evidence that the 51 or above group is

‡Pseudodiploid *v* hyperdiploid $\geq$ 51 *v* all others.

§High risk = leukocyte count > 100 × 10^9/L, mediastinal mass, CNS involvement at diagnosis or E^+ blasts; standard risk = absence of high-risk features.

chromosomally distinct, as first suggested by Kaneko et al,[8] and should be regarded as a unique subset of patients with a better prognosis, except for patients whose karyotypes contain a translocation.

The time-to-failure comparisons in this study indicate that in childhood ALL, translocations as a group convey a poor prognosis. This includes many of the so-called random translocations, which may prove to have a nonrandom (or specific) distribution when larger numbers of cases are studied, as suggested by the finding that the t(11;14) and the t(1;19) correlate with T-cell and pre-B–cell ALL, respectively.[25] Although at least two translocations in other malignancies have been shown to convey a relatively good prognosis [the t(14;18) in follicular small cleaved cell lymphoma and the t(8;21) in ANLL], there has been no similar subgroup identified for ALL in the studies of the Third International Workshop,[6] in those of Bloomfield,[9] or in our studies. Future studies however, may reveal some heterogeneity of response among translocations as additional new subgroups are identified. Likewise new therapies may partially or completely alter the correlation between translocation and prognosis.

It now seems likely that the recognized consistent translocations affect chromosome segments involved in malignant transformation.[29–31] In the present study, the high rate of early failure and poor overall survival of patients with translocations suggest an additional effect, ie, one in which translocations are associated with clinical drug resistance. How this might occur is unclear. One attractive possibility is that translocations increase the proliferative rate of malignant cells, leading to more aggressive disease. Patients with B-cell ALL, characterized by the t(8;14) abnormality or one of the variant forms, have a very poor prognosis and a high leukemic cell proliferative rate.[25] Yet, data reported by us for other immunophenotypes of ALL do not support a proliferative advantage for all leukemic cells with a translocation.[25] To the contrary, in that study, T-cell ALL cases with the 11;14 translocation had a significantly lower percentage of cells in S phase than did those without the translocation. Alternatively, drastic genetic reassortment, typified by translocations, could alter gene expression in ways that might decrease the penetration of drugs into cells or perturb their metabolic fate once they are inside cells.

This study indicates that a translocation is the element within the total karyotype that would be most useful to include in the pretreatment risk assignment for the design of clinical trials in ALL. Chromosome number, or ploidy, appears to be the second strongest feature. It is now possible, in ALL, to obtain analyzable chromosomes and identify abnormal leukemic clones in nearly all cases. Several techniques for the study of bone marrow cells[32–36] are providing good results. In addition, an improved direct technique designed especially for chromosome preparation in ALL is now available, and this method provides a high yield of successfully banded cases, if carefully performed.[10] In our recent experience, it has also allowed identification of chromosomally abnormal lines in a very high percentage of cases analyzed (94%). Recognition of the 51 or above group, especially, may also be achieved by flow cytometric methods and these studies may be used together to confirm and complement each other.[37,38] However, the identification of a translocation depends upon chromosome analysis. Since it may not be possible *in every case* to obtain complete banding and thus recognize or rule out a translocation, the use of either translocation or ploidy may in some situations provide a practical assessment of risk of treatment failure in ALL. We suggest that the presence of any translocation can be used routinely to define high-risk cases. At our institution this karyotypic feature is included with the flow cytometrically determined DNA index, white blood cell count, age, and race for allocation of patients to discrete treatment groups.

ACKNOWLEDGMENT

We wish to thank Dr Costan W. Berard for a valuable critical review of the manuscript; Ann Harris, Kenna Williams, Wanda Lemonds, Terri Huddleston, Jackie Hogan, Ann Tipler, and Susan Hilliard for technical work; Linda Rawlinson, Ann Williford, and Julia Sohm for art work; Linda Burford and Peggy Smith for photographic assistance; John Gilbert for editorial review and critical comments; and the entire staff of the Leukemia-Lymphoma Division for procuring clinical marrow samples.

Monoclonal Antibodies Against SU-DHL-1 Cells Stain the Neoplastic Cells in True Histiocytic Lymphoma, Malignant Histiocytosis, and Hodgkin's Disease

By Su-Ming Hsu, Mark D. Pescovitz, and Pei-Ling Hsu

Three murine monoclonal antibodies, named 2H9, 1E9 and 1A2, were produced after immunization of BALB/c mice with cells of the SU-DHL-1 cell line from a true histiocytic lymphoma. In frozen sections from various lymphomas, 2H9 and 1A2 selectively stained the cell membranes of neoplastic cells in true histiocytic lymphoma and Hodgkin's disease. Antibody 1E9 stained the nuclear membranes of the tumor cells in true histiocytic lymphoma and malignant histiocytosis. No staining was seen in 56 cases of B and T cell lymphoma. Several tissue culture cell lines, including T cell acute lymphoblastic leukemia and pre-B cell lines, were not stained. With 2H9, however, a positive reaction was noted for two Epstein-Barr virus (EBV)-positive African Burkitt's lymphoma cell lines (Daudi and P3HRI), one human T cell lymphoma/leukemia-virus-positive cell line (HUT 102), and one EBV-transformed normal B lymphoblastoid cell line (RPMI 8057). In normal lymphoid tissues, 2H9 and 1E9 reacted with the nuclear membranes of histiocytes and interdigitating reticulum cells, whereas 1A2 stained only rare cells of an unknown type. All three antibodies failed to react with B or T cells in frozen tissue sections of normal lymphoid tissues. The use of these three antibodies should facilitate the diagnosis of histiocyte and interdigitating reticulum (IR) cell-related neoplasms, namely, true histiocytic lymphoma, malignant histiocytosis, and Hodgkin's disease. True histiocytic lymphoma and Hodgkin's disease exhibit similar reactivities with these three and with two other monoclonal antibodies (HeFi-1 and Tac), suggesting that these two types of lymphoma are related. In contrast, malignant histiocytosis was negative for 2H9, 1A2, Tac, and HeFi-1. The difference in the phenotypic expression of true histiocytic lymphoma and malignant histiocytosis indicates that they are two different disease entities.

IT IS NOW recognized that the so-called diffuse "histiocytic" lymphomas (DHL) of the Rappaport classification represent a heterogeneous group of neoplasms originating from B cells, T cells, and true histiocytes.[1] In 50% to 60% of DHL, the cells have characteristics of B lymphocytes; in 5% to 15%, those of T lymphocytes; and in only 5%, those consistent with monocytes or true histiocytes.[1,2] In approximately one-third of the cases, the cells do not have B cell, T cell, or histiocyte characteristics; they have been called "null" cells. With the development of new monoclonal antibodies (MoAbs) and sophisticated immunotyping techniques, however, some of these cases are now being reclassified in either the B or the T cell lineage.

The diagnosis of a B or T cell lymphoma is not difficult, because a large panel of MoAbs specific for either B or T cells is available. However, owing to the lack of antibodies specific for human histiocytes or histiocytic lymphoma cells, the confirmation of a true histiocytic lymphoma is usually not as clear-cut. Although a large number of antibodies against human monocytes are currently available, most of these antibodies do not react with histiocytes or histiocytic lymphoma cells,[3] despite the view that histiocytes and monocytes are closely related.

In this study, we sought to develop histiocyte-specific MoAbs by using cells of the SU-DHL-1 line as the immunogen. The SU-DHL-1 cell line was derived from a patient with histiocytic lymphoma.[4] These cells consistently failed to express T or B cell markers, even after they were induced by phorbol ester (TPA), retinoic acid, dimethylsulfoxide (DMSO), or heme.[3] The SU-DHL-1 cells lack immunoglobulin gene rearrangements.[5,6] They demonstrate cytoplasmic acid phosphatase and nonspecific esterase (ANAE) activities, and they can be stained with a MoAb, anti-Leu M5, that normally reacts with monocytes and histiocytes.[3,7,8] Thus, there is little doubt that SU-DHL-1 is a true histiocytic lymphoma cell line. We report here the production of three MoAbs against the SU-DHL-1 cells. These MoAbs may facilitate the diagnosis of true histiocytic lymphoma (THL) and other histiocyte and interdigitating reticulum (IR) cell-related neoplasms.

MATERIALS AND METHODS

Immunization, cell fusion, and establishment of hybridoma lines. Male BALB/c mice, 8 to 10 weeks old, were immunized intraperitoneally (IP) with 1 × 10^7 SU-DHL-1 cells on days 1, 8, and 15. The fusion protocol was that described by Ozato and colleagues.[9] In brief, on day 18, mouse spleen cells were harvested under sterile conditions and fused with the non-Ig-producing variant myeloma line SP2/0.Ag14 of BALB/c origin. Hybrids were selected in hypoxanthine-aminopterin-thymidine medium. Ten to 14 days after fusion, supernatants from growth-positive wells were screened for binding to SU-DHL-1 cells by the immunocytochemical technique described below. Hybrids of interest were cloned at 1 or 0.5 cell per well on feeder layers of irradiated rat fibroblasts. Ascites was produced by injection of 1 to 2 × 10^6 hybridoma cells IP into BALB/c mice primed with pristane (0.5 mL IP) at least 5 days before the inoculation.

Immunoglobulin (Ig) class typing. The Ig class of the MoAb was determined by the Ouchterlony double-diffusion technique, with class-specific anti-mouse Ig purchased from Litton Bionetics (Kensington, Md).

Preparation of human monocyte-enriched populations. Peripheral blood lymphocytes (PBL) were obtained by Ficoll/Hypaque separation (LSM: Litton) of heparinized whole blood. A monocyte-enriched population was obtained by the method of Falkoff and co-workers.[10] In brief, peripheral blood mononuclear cells were first E rosette-depleted and then incubated with anti-Leu1 MoAb. bit serum was added as a source of complement to lyse cells to which anti-Leu 1 was bound. The enriched population contained 30% to 50% monocytes, which can easily be distinguished from B lymphocytes by the structure of their nuclei. For immunocytochemical staining, the cells were prepared as cytospin smears.

Tissues and cells. Frozen sections of normal lymphoid tissues (tonsils and lymph nodes) and nonlymphoid tissues were prepared as described previously.[11,12] In addition, samples from 29 B cell lymphomas, 27 T cell lymphomas, 15 cases of Hodgkin's disease, 6 THLs, and 6 cases of malignant histiocytosis were obtained for evaluation of the specificity of the antibodies. The diagnosis of B or T cell lymphoma was confirmed by reaction with B or T cell-specific antibodies (Leu 14, B1, lyt3, Leu 1, Leu 2a, Leu 3a, Leu 4, etc.). The diagnosis of THL was based on the following: (a) cytoplasmic acid phosphatase and ANAE activity was abundant; (b) there was no reactivity with any of the B or T cell-specific antibodies; (c) in short-term cultures, the neoplastic cells remained negative for B or T cell markers after induction with TPA, retinoic acid, or heme; (d) the neoplastic cells were capable of phagocytosis of latex particles; and (e) the neoplastic cells formed EA or EAC rosettes. In addition, the diagnosis of malignant histiocytosis was based on its clinicopathologic characteristics, as described by Byrne and colleagues[13] and Scott and colleagues.[14]

The cells were maintained in suspension culture in 10% fetal calf serum (FCS) in RPMI 1640 medium (GIBCO, Grand Island, NY). The SU-DHL-1 cell line was provided by Dr A. Epstein of Northwestern University, Chicago. The Peer, JM, CCRF-H-SB2, and RPMI 8057 cell lines were provided by Dr B. Seon of the University of New York, Buffalo. Other cell lines (listed in Table 1) were obtained from Biotech Research Laboratory, Rockville, Md.

Immunocytochemical technique. The ABC immunoperoxidase technique was applied as described earlier.[15,16] In brief, sections or smears from the various tissues or cells were fixed in acetone for 5 minutes at room temperature. After being washed in Tris-buffered saline (0.01 mol/L of Tris, pH 7.6, 0.15 N NaCl), slides were incubated with MoAbs, followed by biotin-labeled horse antimouse Ig and avidin-biotin-peroxidase complex. Finally, the sections or smears were developed in a peroxidase substrate containing diaminobenzidine, nickel chloride, and H_2O_2. No attempt was made to block endogenous peroxidase activity in eosinophils. The staining of eosinophils, however, did not interfere with the interpretation of results. An immunofluorescence staining method with fluorescein-labeled rabbit anti-mouse Ig was used for detection of the distribution of antigens in HL-60 cells because the localization of endogenous peroxidase activity at the paranuclear region might interfere with the determination of antigens (2H9 and 1E9) in the same area. In some tissues, such as liver, kidney, and pancreas, intrinsic biotin was blocked before immunostaining.[17]

Characterization of specific antigens. For the detection of 2H9, ~5 × 10^7 cultured SU-DHL-1 cells were washed twice with RPMI medium and then lysed on ice for 5 minutes in a buffer containing 20 mmol/L of Tris-HCl, pH 7.2, 0.15 N NaCl, 1% sodium deoxycholate, 1% NP-40, 0.1% sodium dodecyl sulfate (SDS), 10 mmol/L of EDTA, 1 mmol/L of phenylmethyl sulfonyl fluoride (PMSF), and 1% aprotinin (Boehringer Mannheim, Indianapolis). The cell extract was clarified by spinning it for 5 minutes in a microcentrifuge. For the detection of 1E9, stepwise extractions of proteins were carried out with: (a) 1% NP40 in Tris-saline, 1 mmol/L of PMSF; (b) 0.6 mol/L of potassium acetate, pH 5.5, 1 mmol/L of PMSF; and (c) 2 mol/L of potassium acetate, 5 mol/L of urea, 10 mmol/L of Tris, pH 7.5, and 1 mmol/L of PMSF. The concentrations of proteins in the extracts were determined by the method of Bradford.[18] For immunoblots, proteins in Laemmli sample buffer (15 μg per lane) were loaded on a 10% SDS polyacrylamide gel and electrophoresed.[19] Before transfer, the gel was soaked in 4 mol/L of urea and 0.1 mol/L of DTT for 20 minutes and then in transfer buffer (20% methanol, 14.4 g/mL of glycine, 3 g/mL of Tris) for 10 minutes. BA 85 nitrocellulose (0.2 μm, Scheicher and Schull) was used as the blotting membrane. For the detection of total transferred proteins, one strip of nitrocellulose was stained with 0.5% fast green in 20% methanol and 5% acetic acid, and then destained. For detection with MoAbs, the filter was first blocked with normal horse serum (1:200 dilution, from Vector stain ABC kit) in a buffer containing 3% nonfat dry milk in TS (20 mmol/L of Tris, pH 7.6, 0.15 N NaCl) for 30 minutes. After being washed with TS plus 0.1% Triton X-100 (TST, Research Products International, Elk Grove, Ill), the filter strips were incubated with MoAbs (one per strip) for 3 hours and then treated as follows: (a) three washes with TST, (b) 30-minute incubation with biotin-labeled horse anti-mouse (1:200) reagent, (c) three washes with TST, or (d) 30-minute incubation with avidin-biotin-peroxidase complexes (Vector ABC). After a last washing with TST, the filter strips were developed with 4-chloro-1-naphthol (stock 3 mg/mL in methanol, diluted 1:5 in PBS prior to use) and H_2O_2.

Table 1. Reactivities of the Three Monoclonal Antibodies Studied With Lymphoma or Normal B Cell Lines

Cell Line	2H9	1A2	1E9
T cell lymphoma			
HUT-78	–	–	–
HUT-102	+ (m)	–	–
Burkitt's lymphoma			
Raji	–	–	–
Daudi	+ (gr)	–	–
P3HR-1	+ (gr)	–	–
B lymphoblastoid cell			
RPMI 8057	+ (m)	–	–
Monocyte/histiocyte lymphoma			
U-937	5% to 10% + (nm)	–	5% to 10% + (nm)
SU-DHL-1	+ (m)	+ (m)	+ (c)
HL-60*	+ (nm)	–	+ (nm)

m, cell membrane; gr, granular; nm, nuclear membrane; c, cytoplasm.

Other virus-negative B or T lymphoma cell lines, including KM-3/REH, NALM-16, NALM-1JR, HPB-NULL, NALL-1, Peer, JM, Molt-3, Molt-4, CEM, Jarka, and CCRF-HS-B-2 exhibit no reactivity with these three antibodies.

*The staining pattern of HL-60 cells remained the same when the cells were induced by exposure to TPA (2 ng/mL) for 48 hours.

RESULTS

Identification of hybridoma supernatants binding to SU-DHL-1 cells. Immunocytochemical assay of supernatants from the growth-positive wells yielded 54 cultures (11%) which produced antibodies capable of staining SU-DHL-1 cells on cytospin slides. The positive, undiluted supernatants were rescreened with frozen sections of normal tonsils so that their reactivities with normal lymphoreticular cells could be determined. Antibodies that reacted with all lymphoid cells or that produced high background or nonspecific (nondiscriminative) staining were eliminated. Three of the supernatants were selected based on their strong reactivity with SU-DHL-1 cells, but minimal reactivity with normal lymphoid tissues. The corresponding cells were expanded and subcloned at 0.5 cell per well, and the MoAbs were named 2H9, 1E9, and 1A2. Both 2H9 and 1A2 stained the cell membranes of SU-DHL-1 cells, whereas 1E9 elicited an intracytoplasmic granular reaction in the juxtanuclear region.

The isotype of all three MoAbs was determined to be IgM κ by the Ouchterlony double-diffusion technique.

Binding of 2H9, 1E9, and 1A2 to peripheral blood mononuclear cells and normal lymphoid tissues. None of the three MoAbs reacted with B or T lymphocytes in the peripheral blood or in lymphoid tissues such as lymph nodes, tonsils, and spleens.

Antibodies 1E9 and 2H9 stained monocytes in peripheral blood. The former elicited an intracytoplasmic punctate reaction (Fig 1A), whereas the latter produced nuclear membrane staining of variable intensity (Fig 1D); 1E9 also reacted with the cytoplasm of granulocytes (Fig 1A, arrow), whereas 1A2 did not react with either monocytes or granulocytes.

In normal lymphoid tissues, including tonsils and lymph nodes, 1E9 and 2H9 were very similar in their staining pattern; both reacted with the nuclear membranes of histiocytes and of IR cells (Fig 1B and E). We confirmed this reactivity with IR cells by examining lymph nodes from two patients with dermatopathic lymphadenitis, which contained abundant IR cells (Fig 1C). Antibody 1A2 reacted only with rare cells scattered in the lymphoid tissue (Fig 1F). The nature of the 1A2-positive cells is not known; however, some appeared to be tingible-body macrophages in the germinal centers.

Binding of 2H9, 1E9, and 1A2 to tissue culture cell lines. Table 1 shows the reactivities of 2H9, 1E9, and 1A2 with human leukemia cells, lymphoma cells, and normal cell lines. 1A2 did not bind to any of the cells except SU-DHL-1, whereas 1E9 and 2H9 reacted with monocyte/granulocyte/histiocyte cells of lines such as U-937, SU-DHL-1, and HL-60. These reactivities were not unexpected, because 2H9 and 1E9 reacted with monocytes/histiocytes in normal lymphoid tissues (Fig 1A and D); 2H9 also reacted with several virus-positive cell lines. These include: (a) the human T-cell leukemia/lymphoma virus (HTLV)-positive line, HUT 102; (b) two EBV-positive African Burkitt's lymphoma cell lines, Daudi and P3HR1; and (c) an EBV-transformed B lymphoblastoid cell line, RPMI 8057. The staining of 2H9 and 1A2 with the cell membrane of SU-DHL-1 cells was confirmed by flow cytometry and immunoelectronmicroscopy.

Binding of 2H9, 1E9, and 1A2 to lymphomas. Table 2 shows the reactivities of the MoAbs with lymphoma cells in frozen sections when the ABC immunohistochemical technique was used. None of the antibodies stained B or T cell lymphomas (56 cases were studied). Both 2H9 and 1A2 reacted with the cell membrane of Hodgkin's mononuclear cells and Reed-Sternberg cells (H-RS cells) in all 16 cases of

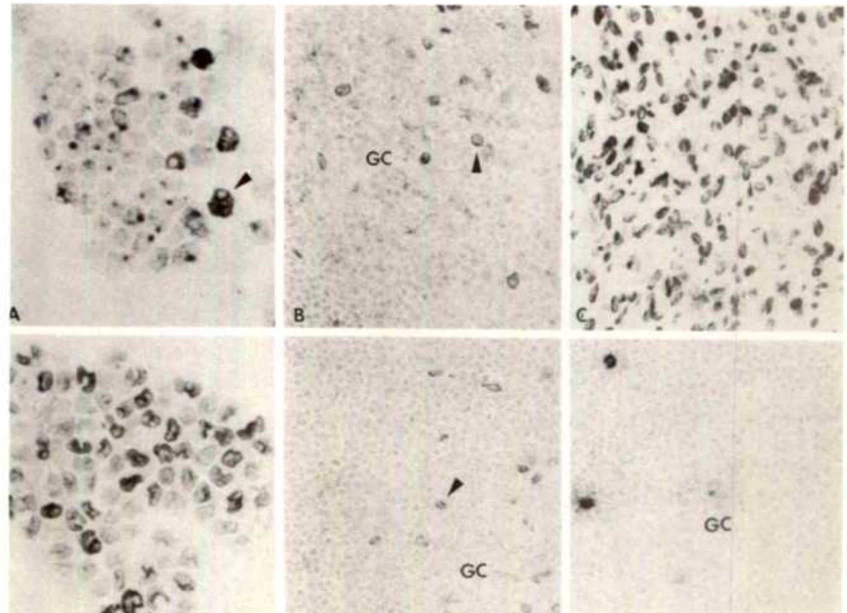

Fig 1. **(A) 1E9 staining of a smear of a monocyte-enriched fraction of PBL, (B) a frozen section of a tonsil, and (C) a frozen section of a lymph node from a patient with dermatopathic lymphadenitis. 1E9 shows an intracytoplasmic granular staining pattern in monocytes. It also reacts with granulocytes (arrow, A). In frozen sections, 1E9 stains the nuclear membrane of histiocytes (arrow, B) and (C) of interdigitating reticulum cells. (D) 2H9 staining of a smear of a monocyte-enriched fraction of PBL and (E) a frozen section of a tonsil. Note difference in staining patterns of monocytes with 2H9 (D) and 1E9 (A). The histiocytes in germinal centers (GC) (arrow, E) are stained by 2H9; (F) 1A2 reacts with rare cells in a section of tonsil (A,D ×400; B,C,E,F ×250.).**

Table 2. Reactivities of Monoclonal Antibodies With Lymphomas

Lymphoma	No. of Cases	2H9	1A2	1E9
B cell lymphoma*	29	–	–	–
T cell lymphoma†	27	–	–	–
True histiocytic lymphoma	6	+	+	+*
Malignant histiocytosis	6	–	–	+*
Hodgkin's disease	16			
Nodular sclerosis	11	+	+	–
Mixed cellularity	4	+	+	–
Lymphocyte predominant	1	+	+	–

*The B cell lymphomas examined include well-differentiated lymphocytic lymphoma (5); intermediately differentiated lymphoma (3); follicular lymphoma, poorly differentiated (5); follicular lymphoma, mixed cellularity (3); small-cell undifferentiated, non-Burkitt's (3); and diffuse large cell lymphoma (10).

†The T cell lymphomas examined included mycosis fungoides (10), peripheral T cell lymphoma (15), and lymphoblastic lymphoma (2).

Hodgkin's disease (Fig 2B). The staining intensity was greater with 2H9 than with 1A2. Although 1E9 failed to stain H-RS cells in tissue sections, it reacted with H-RS cells in short-term cultures, showing an intracytoplasmic granular staining pattern (data not shown).

In all six cases of THL studied, 2H9 and 1A2 stained the cell membrane (Fig 2) and 1E9 stained the nuclear membrane (Fig 3) of the neoplastic cells. In six cases of malignant histiocytosis, 1E9 also stained the nuclear membrane of the neoplastic cells (Fig 3B), whereas 1A2 and 2H9 were negative.

Staining of normal nonlymphoid tissues. Table 3 summarizes the results of staining in various normal, nonlymphoid tissues: 1A2 did not react with any of the tissues examined, and no reactivity with 2H9 was detected except in the cytoplasm of the squamous epithelium in tonsils and in the nuclear membrane of endothelial cells. In contrast, 1E9 stained the nuclear membrane of many nonlymphoid cells, such as the epithelial cells in the thyroid and prostate, as well as endothelial cells.

Identification of the antigens recognized by 2H9, 1E9, and 1A2. Cells from SU-DHL-1 cultures were lysed with detergent or extracted with high salt and urea, and the proteins recognized by the MoAbs were analyzed by the immunoblot technique, as described in the Materials and Methods section. Figure 4 shows that 2H9 recognized a protein of 110 kd in the detergent lysate of SU-DHL-1 cells (Fig 4). A control MoAb, M318, reproducibly recognized a protein of 37 kd, but 1A2 and 1E9 failed to identify any specific protein from the same cell lysate. An alternative extraction procedure with 2 mol/L of potassium acetate and 5 mol/L of urea revealed a 61-kd protein that was recognized by 1E9 (Fig 5). This protein was not present in significant amounts in the 1% NP40 lysate or in the 0.6 mol/L of potassium acetate extract of the SU-DHL-1 cells.

DISCUSSION

Three murine MoAbs, 2H9, 1A2, and 1E9, were produced after immunization of BALB/c mice with the SU-DHL-1 THL cell line. None of the three MoAbs reacted with B cell or T cell lymphomas in frozen tissue sections. They appear to be useful for the diagnosis of histiocyte or IR cell-related lymphomas. However, the diagnostic usefulness of these new MoAbs resides in the differential staining patterns which they exhibited. MoAbs 2H9 and 1A2 stained the cell membranes of neoplastic cells from patients with THL and Hodgkin's disease, whereas IE9 stained the nuclear membranes of the tumor cells in malignant histiocytosis and THL.

The discovery (with 2H9 and 1A2) of a common phenotype between THL cells and H-RS cells is not totally unexpected, however, inasmuch as H-RS cells have been shown to display features of histiocytes/macrophages.[20,21] In this study, despite the difference in the subcellular distribution of antigens (ie, cell membrane in H-RS cells *v* nuclear membrane in histiocytes/IR cells), the reactivity of 2H9 provides additional evidence for a histiocyte/IR cell lineage of H-RS cells.[22]

In contrast to the cells in THL, the neoplastic cells of malignant histiocytosis do not express 2H9 and 1A2, but do express 1E9. In recent years, there has been much dispute as to whether THL and malignant histiocytosis are two distinct disease entities. These two lymphomas present a similar histological picture, but differ in their clinical course. The present study indicates that THL cells and malignant histiocytosis cells can be distinguished on the basis of the differential expression of 2H9, 1A2, and 1E9. In other studies, we have also shown that the neoplastic cells of malignant histiocytosis may express OK M1, Mo2, or Leu M5, especially when the malignant histiocytosis cells are induced by a phorbol ester. THL cells, in contrast, do not express these monocyte markers, even with TPA induction.[3]

The difference in the subcellular distribution of the three

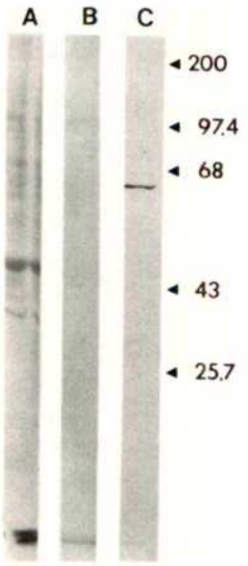

Fig 5. Immunoblot detection of antigen 1E9. An extract (2 mol/L of potassium acetate and 5 mol/L of urea) of SU-DHL-1 cells was electrophoresed on a 10% sodium dodecyl sulfate gel, electroblotted onto a nitrocellulose filter membrane, and reacted with specific monoclonal antibodies. antigens is of interest. For example, 2H9 appears to react with the cell membranes of H-RS cells and SU-DHL-1 cells, whereas in U-937 (a malignant histiocytosis cell line) and HL-60 (a promyelocytic cell line), a nuclear-membrane staining pattern was observed. We have also found that 1E9 reacts with the nuclear membrane of histiocytes, IR cells, THL cells, and malignant histiocytosis cells in tissue sections, whereas it reacts mainly with a localized area of the cytoplasm of "cultured" SU-DHL-1 or H-RS cells (1E9 did not stain H-RS cells in sections). Staining of U-937 cells with 1E9 normally is observed on the nuclear membrane of ~5% to 10% of these cells, but the 1E9 staining becomes cytoplasmic when the cells are induced with TPA.[3]

Either synthesis of new proteins or redistribution of existing proteins may be responsible for the altered staining pattern. These events may be related to the difference in the status of differentiation or in the cellular environment between cells in cultures or in tissues or between tumor cells and normal cells. We do not know whether 2H9 antigens located in the nuclear membrane and cell membrane are identical. Although some virus-infected cells express viral proteins on nuclear and cell membranes simultaneously, the 2H9, 1A2, and/or 1E9 determinants are not likely to be viral, because they exist in normal histiocytes and IR cells. In animal cells, the outer nuclear membrane is continuous with the endoplasmic reticulum (ER). Like rough ER, the outer nuclear membrane is often studded with ribosomes engaged in protein synthesis. Furthermore, the perinuclear space is continuous with the lumen of the ER. Both the perinuclear space and the outer nuclear membrane can be regarded as a small, specialized region of ER. Therefore, the presence of antigens on the nuclear membrane is not totally unexpected. Future studies of anomalous antigen distributions of these lymphoma cells may provide an understanding of the neoplastic process.

Although both 2H9 and 1E9 react with the nuclear membranes of histiocytes and IR cells, these two antibodies recognize different antigens: 2H9 recognized a 110-kd antigen isolated from SU-DHL-1 cells, whereas 1E9 recognized a 61-kd antigen that was identified in the high salt and urea extract of cells. It should be noted that although 1E9 stains the cytoplasm of SU-DHL-1 cells, the staining is localized. Because this 61-kd protein cannot be extracted with NP-40 or 0.6 mol/L of potassium acetate, it appears that the 1E9 molecules are not soluble and do not diffuse freely in the cytoplasm. It is likely that 1E9 is tightly associated with the cytoskeleton or with a membrane component in the cytoplasm of SU-DHL-1 cells. Whether this 61-kd protein originates in the nuclear membranes of the precursor cells (such as histiocytes or IR cells which show nuclear membrane staining) remains to be clarified.

The antigen recognized by 1A2 has not yet been identified; 1A2 may fail to react with the antigen due to denaturation of antigen under the experimental conditions used (such as detergent, heat, pH, etc.) When we attempted immunoprecipitation by using an S-methionine-labeled cell extract, we were unable to identify the protein recognized by 1A2. Moreover, for glycolipid antigens, an approach other than SDS gel electrophoresis may have to be used.

One unexpected finding of this study is that although 2H9 does not react with most B or T cell lymphomas or cell lines, it does react with some virus-transformed cell lines, such as HUT-102 (HTLV-I +), RPMI 8057, Daudi, and P3HR-1 (EBV+). The reason for this reactivity is not known. It should be noted that HeFi-1, an H-RS cell-specific antibody, also stains EBV-transformed B lymphoblastoid cell lines and HUT-102.[23] However, since these virus-positive T/B cell lines consistently express B or T cell markers, their cross-reactivity with 2H9 and HeFi-1 does not pose any diagnostic problems. We would like to emphasize that the 2H9-positive H-RS or THL cells also express other histiocyte or IR cell markers (ie, 1E9, Leu M1) and never express B or T cell antigens, even when these cells are induced with phorbol ester.[3] The 2H9 (mol wt 110 kd) and HeFi-1 (mol wt 120 kd) determinants do not seem to be identical, since only the 2H9 determinant can be modulated in the presence of antibody (Hsu et al, unpublished data).

In conclusion, we have obtained MoAbs that can be used for the differential diagnosis of histiocyte or IR-cell-related lymphomas. Previously, various diagnostic tests (ie, enzyme cytochemistry, detection of Fc or complement receptors, detection of lysosomal enzymes, and phagocytic assays) have been used for the diagnosis of THLs.[1,2,24] However, none of these methods has proved satisfactory because of lack of specificity and sensitivity. Although it is generally recognized that histiocytes and monocytes are related, the currently available monocyte-specific MoAbs, such as OK M1, Mo2, Leu M2, and Leu M3 do not react with the neoplastic cells of THL, and they cannot distinguish THL from other large cell lymphomas.[25] The three MoAbs (2H9, 1E9, and 1A2) that we have described appear to be useful not only for the diagnosis of THL but also for malignant histiocytosis and HD. Because these MoAbs react extremely rarely with the normal cell membranes of lymphoid or nonlymphoid cells, it may be possible to use them as effective agents for therapy or immunoimaging in the near future.

Primary Systemic Amyloidosis: Multivariate Analysis for Prognostic Factors in 168 Cases

By Robert A. Kyle, Philip R. Greipp, and W. Michael O'Fallon

One hundred sixty-eight patients with primary systemic amyloidosis (AL) were identified. Median survival after diagnosis was 12 months and ranged from 4 months for patients presenting with congestive heart failure to 50 months for those presenting with peripheral neuropathy only. Utilizing the proportional-hazards model in a stepwise multivariate fashion to evaluate the simultaneous influence of putative risk factors as of diagnosis revealed that congestive heart failure, urine light chain, hepatomegaly, and multiple myeloma were the major factors adversely affecting survival during the first year after diagnosis. Serum creatinine, multiple myeloma, orthostatic hypotension, and monoclonal serum protein were the most important variables adversely affecting survival for patients surviving 1 year. These models were used to categorize patients according to the variables in the models into low-, moderate-, and high-risk groups for the first year after diagnosis and separately for subsequent years. The influence of these variables on survival is important in stratification of patients randomized to prospective clinical trials.

© 1986 by Grune & Stratton, Inc.

ALTHOUGH amyloidosis has been recognized for more than a century, there has been no analysis of prognostic factors. Amyloid, a substance that appears to be homogeneous and amorphous under the light microscope, consists of rigid, linear, nonbranching aggregated fibrils. The fibrils consist of the variable portion of a monoclonal light chain, are arranged in a β-pleated sheet formation, are insoluble, generally resist proteolytic digestion, and constitute the amyloid deposits that replace and destroy normal tissues. Except for multiple myeloma, which is seen in about one-fifth of the patients with primary amyloidosis (AL), patients have no evidence of preceding or coexisting disease responsible for the amyloidosis.

In two series of patients with primary amyloidosis (AL), the median survival after histologic diagnosis of amyloid was approximately 1 year.[1,2] This short survival and the lack of an analysis of prognostic factors in primary amyloidosis (AL) prompted us to undertake this study.

MATERIALS AND METHODS

All Mayo Clinic records reporting a histologic diagnosis of amyloidosis from Jan 1, 1970, to Dec 31, 1980, were reviewed, and the data were abstracted on sheets suitable for keypunching. All laboratory data were obtained from Mayo Clinic records within 1 month of the histologic diagnosis of amyloidosis. All parameters were measured in all patients. The data for multiple visits were recorded on separate sheets, and a longitudinal view was obtained. Patients with secondary amyloidosis or with localized, familial, or senile amyloidosis were excluded. Patients with amyloidosis and multiple myeloma were included because dfferentiation on this basis is often difficult inasmuch as these conditions represent the same fundamental process. In a recent report,[3] the presence or absence of myeloma in patients with amyloidosis did not influence survival. All patients were followed up until death or for at least 1 year after the diagnosis of amyloidosis.

Standard univariate statistical methods were used to summarize the distribution of each of the parameters. Survival curves were estimated by the Kaplan-Meier technique.[4] The proportional-hazards method of Cox was used to determine the variables that influenced survival separately for the first year after diagnosis and for subsequent years.[5]

RESULTS

One hundred sixty-eight patients with primary systemic amyloidosis (including 40 with multiple myeloma) were identified (Table 1). Amyloidosis was diagnosed on the basis of finding amyloid deposits in tissue by the use of appropriate staining procedures or of demonstrating amyloid fibrils with electron microscopy. Seventy percent of the patients had a positive rectal biopsy. Biopsies of the kidney, small intestine, and sural nerve were positive in 83% to 100% of specimens studied.

Loss of weight was noted in 42% of the patients; the amount of the loss contributed significantly to the prediction of early survival. Among those who lost weight, the loss ranged from 2.3 to 40.9 kg (5 to 90 lb), with a median of 9.1 kg (20 lb). Fatigue was common, being found in 55% of the 168 patients. Purpura was found in 15% and gross bleeding in 9%. Some patients had more than one symptom.

The liver was palpable in one-third of the patients but extended more than 10 cm below the right costal margin in only two. The spleen was palpable in only 4% and was modest in size; none extended >3 cm below the left costal margin. Macroglossia, present in one-fourth of the patients, occasionally constituted the major manifestation of the disease. Lymphadenopathy was infrequent.

The syndromes present at the time primary systemic amyloidosis was diagnosed are listed in Table 2. Nine patients (5.3%) had a malabsorption syndrome. Symptoms of nephrotic syndrome and congestive heart failure existed approximately 1 to 3 months before the diagnosis of amyloidosis, while symptoms of peripheral neuropathy or carpal tunnel syndrome were present for approximately a year before amyloidosis was diagnosed. Congestive heart failure and orthostatic hypotension frequently developed during the patient's illness.

Laboratory studies. Anemia was not a prominent finding, the initial median hemoglobin value being 12.7 g/dL. Of

Table 1. Age and Sex Distribution of 168 Patients With Primary Systemic Amyloidosis (AL)

Age (yr)	Males	Females	Total No.	Total %
<40	2	0	2	1
40-49	11	6	17	10
50-59	29	15	44	26
60-69	30	25	55	33
70-79	31	13	44	26
≥80	6	0	6	4
Total*	109 (65%)	59 (35%)	168	100

*Median, 64 years.

the 18 patients with an initial level <10 g/dL, 8 had multiple myeloma, 8 had renal insufficiency, 1 had gastrointestinal bleeding, and 1 had no apparent cause. Leukopenia was found in only 1%, thrombocytopenia in 1%, and thrombocytosis (> 500,000/mm^3) in 7%. Renal insufficiency was evident initially in 55% of the males and 59% of the females. Twenty-six percent of the males and 12% of the females had an initial creatinine level > 2.0 mg/dL.

Serum protein findings. More than half of the patients had either hypogammaglobulinemia or a normal serum protein electrophoretic pattern. A localized band or spike was found in 74 patients, and when present, it was usually of only modest size (median, 1.3 g/dL). Immunoelectrophoresis revealed a monoclonal serum protein in 69%. Unexpectedly, 26% of the patients had a free monoclonal light chain in the serum (Bence Jones proteinemia). Lambda light chains predominated (λ in 83 and κ in 31 cases).

Urine protein findings. Proteinuria (routine urinalysis) was found in 80% of the patients. Electrophoresis of concentrated urine revealed a globulin band in two-thirds of the patients and an albumin peak in more than 70%.

Immunoelectrophoresis of an adequately concentrated urine specimen showed a monoclonal light chain in 75% of the patients during their disease. In two-thirds of the patients, the light chains were λ. A monoclonal protein was found in the serum or urine in 89% of the patients.

Other studies. Bone marrow plasma cell counts ranged from 1% to 99%, with a median of 9%. Roentgenograms were normal in 62% of the patients. Osteolytic lesions were found in 15 patients; all had overt multiple myeloma.

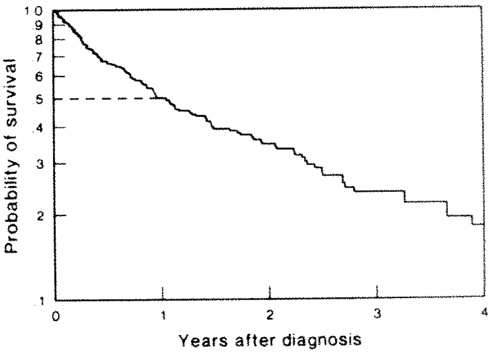

Fig 1. Probability of survival after diagnosis of primary systemic amyloidosis (AL).

Therapy and cause of death. Eighty-four percent of the patients received an alkylating agent some time during their illness. Colchicine was given to 13 patients. Nineteen patients did not receive any therapy. Cardiac involvement accounted for 40% of the deaths, but the percentage was probably higher because many patients who died of "amyloidosis" may have died of cardiac disease. Only 1 patient died of another malignancy—malignant melanoma.

Survival by syndromes. Median survival of the 168 patients after the diagnosis of amyloidosis was 12 months (Fig 1). All patients were followed up, if alive, for at least 1 year, and, as of the last follow-up, 79% had died. In contrast, the estimated median survival from diagnosis of amyloidosis to death for patients presenting with various syndromes ranged from 4 months for those presenting with congestive heart failure to 50 months for those presenting only with peripheral neuropathy (Table 3). Death of patients presenting with only the carpal tunnel syndrome or peripheral neuropathy (or both) was due to eventual involvement of other organs.

Seventeen of the 54 patients presenting with a nephrotic syndrome also had either congestive heart failure or orthostatic hypotension at presentation. Nine of the 54 survived more than 3 years after the diagnosis of amyloidosis, and only 2 of them are now known to have died, 1 of malignant

Table 2. Syndromes at Time of Diagnosis of Primary Systemic Amyloidosis (AL)*

Condition	At or Before Diagnosis of Amyloidosis No.	At or Before Diagnosis of Amyloidosis %	Month Before Diagnosis of Amyloidosis Median	Month Before Diagnosis of Amyloidosis Range	No. After Diagnosis of Amyloidosis	Total No.	Total %
Congestive heart failure	38	23	3.5	0-12	19	57	34
Nephrotic syndrome	54	32	1.5	0-36	6	60	36
Carpal tunnel syndrome	46	27	9.2	0-227	1	47	28
Orthostatic hypotension	23	14	6.2	0-39	9	32	19
Peripheral neuropathy	28	17	12.8	0-58	1	29	17

*Some patients had more than one condition.

Table 3. Survival by Presenting Symptoms of 168 Patients With Primary Systemic Amyloidosis (AL)

	Patients	Median Survival (mo)
Total group	168	12
Hierarchical groups*		
Congestive heart failure	38	4
Orthostatic hypotension	17	12
Nephrotic syndrome	37	16
Carpal tunnel syndrome	28	23
Peripheral neuropathy	11	50

*Patients were placed only in the first group they occurred in. Thus, none of the 37 patients listed as presenting with a nephrotic syndrome had either congestive heart failure or orthostatic hypotension, but some may have had the carpal tunnel syndrome or peripheral neuropathy.

Table 5. A Model Involving Five Variables Related to Survival During First Year After Diagnosis of Primary Systemic Amyloidosis (AL)

Variable	Coefficient	*P* Value
Congestive heart failure (CHF)	1.43	<0.0001
Urine light chain (ULC)	0.97	0.0064
Hepatomegaly (HEP)	0.58	0.0106
Multiple myeloma (MM)	0.65	0.0126
Monoclonal serum protein (MCS)	−0.87	0.0008

melanoma and 1 of suicide. One patient continues on dialysis more than 12 years after diagnosis. Only 3 patients who had congestive heart failure at presentation survived more than 2 years.

Analysis of survival. Because the assumption of proportional-hazards functions was not satisfied over the entire follow-up period but did hold separately within the first year and subsequently, the proportional-hazards method of Cox was used separately for these two periods in an attempt to evaluate the influence of the variables on survival. Coincidentally, half of our patients were dead at 1 year.

Analysis of survival during the first year. Four variables—congestive heart failure (CHF), urinary light chain (ULC), hepatomegaly, and amount of weight loss—had a highly significant influence on survival during the first year (Table 4). Four other variables (albuminuria, elevated serum creatinine, sex, and myeloma) were significant ($P < 0.05$).

The proportional-hazards model was then employed in a step-wise multivariate fashion to evaluate the simultaneous influence of combinations of the variables. The first three variables that were entered into the model, and their *P* values on entry, were CHF ($P < 0.0001$), ULC ($P = 0.0001$), and MCS (monoclonal serum protein) ($P = 0.009$).

When the step-wise process was allowed to continue without concern for the implications of the limited data available in some subsets of patients, hepatomegaly and multiple myeloma were identified as having an additional effect on survival ($P < 0.05$) after the effects of the first three variables had been accounted for.

The possibility that some of these five variables interact with each other in their influence on survival cannot be denied. However, the numbers of patients with combinations of variables is too small to address the question of such potential interactions in a satisfactory manner. The model (Table 5) summarizing the influence of the five variables assumes no interactions among them, and therefore the joint influences predicted by the model are based on the distribution of the individual variables, and predictions are possible, even when data are sparse.

The coefficients of the variables in this model suggest that a diagnosis of CHF is highly detrimental to survival, the presence of ULC somewhat less detrimental, the presence of HEP and MM about equal and even less detrimental, and the presence of MCS actually "protective." This model was used to create a gradient of risk, and three classes of patients were defined according to this gradient. These classes, referred to as low, moderate, and high risk, are defined as (1) low risk: Patients with no factors or MCS alone or MCS and one of HEP, MM, ULC. (2) Moderate risk: Patients with one of HEP, MM, ULC or MCS and two of HEP, MM, ULC or MCS and CHF. (3) High risk: Patients with CHF alone or all factors except CHF or CHF with or without MCS with one or more of HEP, MM, ULC or two or more of HEP, MM, ULC.

When the 168 patients were classified according to these definitions, there were 60 patients in the high-risk group, 70 in the low-risk group, and 48 in the moderate-risk group. The Kaplan-Meier estimates of the survival curves for these three

Table 4. Effect of Individual Variables on Survival Curves

During First Year		After First Year	
Variable	*P* (log-rank)	Variable	*P* (log-rank)
Congestive heart failure	.0001	Hemoglobin	.0022
Urinary light chain	.0001	Serum creatinine	.0023
Hepatomegaly	.0002	Myeloma	.0037
Weight loss (amount)	.0055	Monoclonal serum protein	.0370
Electrophoretic pattern of albumin in urine	.0108	Urinary light chain	.0540
Elevated serum creatinine (>2.0 mg/dL)	.0270		
Sex	.0320		
Myeloma	.0420		

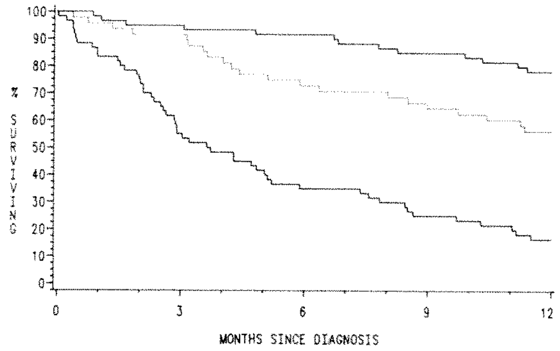

Fig 2. Kaplan-Meier estimates of the survival curves for low-, moderate-, and high-risk patients with primary systemic amyloidosis (AL).

classes are illustrated in Fig 2. The three curves are significantly different ($P < 0.0001$, log-rank test) and demonstrate a clear classification of the patients into three groups according to likelihood of surviving 1 year after a diagnosis of amyloidosis.

Analysis of survival after 1 year. The proportional-hazards model was also used to identify variables whose value at diagnosis influenced the rate of subsequent mortality among the 84 patients who survived 1 year after diagnosis (Table 4). Hemoglobin level, serum creatinine level, and presence of multiple myeloma have a highly significant influence on survival ($P < 0.005$), with MCS and ULC being of borderline significance.

As before, the proportional-hazards model was used in a step-wise multivariate fashion to evaluate the simultaneous influence of several variables on survival and/or to evaluate the influence of a variable after the influence of other variables has been taken into account.

In the modeling process, hemoglobin and serum creatinine levels appeared to be surrogates of each other, and the final model ($P < 0.0001$) included serum creatinine, multiple myeloma, orthostatic hypotension, and monoclonal protein in the serum (Table 6). Although no interactions were found to be significant, the sample size limits our ability to detect them. As before (in reference to year 1), the model is used to establish a gradient of risk, and three classes of patients are defined on the basis of the values of the four variables at the time of the diagnosis of amyloid and referred to as low, moderate, and high risk. These classes are (1) low risk: Serum creatinine ≤ 2.0 and no risk factors (MM, OH, MCS); (2) moderate risk: Serum creatinine 2.0 to 6.5 and no risk factors or serum creatinine < 2.0 and either MM or MCS; (3) high risk: Serum creatinine > 6.5 and no risk factors or serum creatinine > 2.0 and either MM or MCS or OH alone or two or more of MM, MCS, OH.

Of the 84 patients who survived 1 year after the diagnosis of amyloid, 14 were in the low-risk group, 38 in the moderate-risk group, and 32 in the high-risk group. Figure 3 illustrates the estimated survival curves (Kaplan-Meier) for these three groups. The curves differ significantly ($P < 0.0001$, log-rank test).

DISCUSSION

In three series comprising almost 500 cases of primary systemic amyloidosis (AL) from the Mayo Clinic, the median survival was 14.7 months or less.[1,2,6] Daniels and Hewlett[7] reported that the median survival of patients with primary amyloidosis was 5 months, while in another series,[8] no patients with primary amyloidosis (AL) survived more than 12 months after diagnosis. In a series of 32 patients with primary systemic amyloidosis with or without myeloma, the median survival was 14 months.[3] In 1976, Pruzanski and Katz[9] reported a mean survival of 28 months for 26 patients with primary amyloidosis who had died.

Table 6. Variables Affecting Survival After First Year Following the Elimination of Hemoglobin in Cases of Primary Systemic Amyloidosis (AL)

Variable	Coefficient	*P* Value
Serum creatinine	0.21	0.0001
Multiple myeloma (MM)	1.07	0.0014
Orthostatic hypotension (OH)	1.75	0.0007
Monoclonal serum protein (MCS)	1.04	0.0065

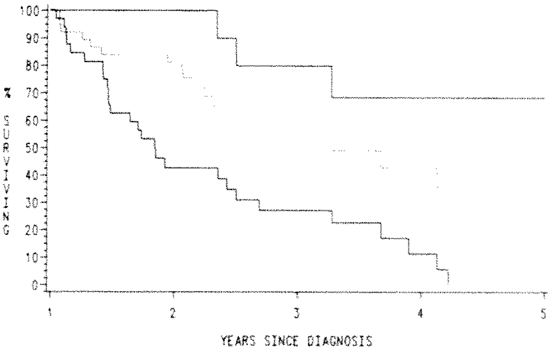

Fig 3. Kaplan-Meier estimates of the survival curves for low-, moderate-, and high-risk patients with primary systemic amyloidosis (AL) who survived 1 year after diagnosis.

The median survival from diagnosis of amyloidosis to death among the current series of 168 patients presenting with associated syndromes ranged from 4 months in those presenting with congestive heart failure to 50 months in those presenting only with peripheral neuropathy. It should be pointed out that the patients presenting only with peripheral neuropathy or the carpal tunnel syndrome who died usually did so from subsequent cardiac or renal involvement. In fact, cardiac involvement accounted for the deaths of 40% of the patients who died.

The median survival of the 168 patients in our series was 12 months. The major risk factor for survival during the first year was the presence of congestive heart failure. The presence of hepatomegaly, urinary light chain, and multiple myeloma also had an adverse effect on survival during the first 12 months. The presence of a monoclonal protein appeared to have a "protective" effect on survival but only during the first year. An explanation of this phenomenon is not readily available. Utilization of these variables allowed us to categorize the patients into low risk, moderate risk, or high risk the first year after diagnosis. Patients in the high-risk group had a median survival of 3.5 months, in contrast to more than 1 year for those in the low- or moderate-risk groups.

Utilization of the proportional-hazards model in a stepwise multivariate fashion revealed that after the first year, patients with more severe systemic amyloidosis had died and that serum creatinine levels, multiple myeloma, orthostatic hypotension, and monoclonal serum protein in the urine were the most important variables affecting survival. Patients in the high-risk group had a median survival of 10 months after the first year (total, 22 months), whereas the median survivals in the low- and moderate-risk groups exceeded 28 months after the first year (total, 40 months). It should be emphasized that the significant variables influencing survival during the first year after diagnosis—congestive heart failure, urinary light chain, hepatomegaly, and loss of weight—had a negligible role in affecting survival after the first year.

This study permits a more accurate assessment of survival at the time of diagnosis of primary systemic amyloidosis. The influence of these variables on survival is important in the stratification of patients randomized to prospective clinical trials.

Functional Characterization of Platelet-Bound Factor XIa: Retention of Factor XIa Activity on the Platelet Surface

By Peter N. Walsh, Dipali Sinha, Alice Koshy, Frances S. Seaman, and Harlan Bradford

Previously we have shown that both factor XI and factor XIa are bound specifically to distinct, high-affinity sites on the surface of activated platelets in the presence of high Mr kininogen. To determine the functional significance of factor XIa binding to platelets, bound factor XIa has now been compared with the unbound enzyme. Platelets incubated with thrombin, high Mr kininogen, and ^{125}I-labeled factor XIa bound 130 to 500 molecules of factor XIa per platelet. Scatchard analysis of binding data give a dissociation constant (Kd) of 822 pmol/L ± 140 (SEM). Rates of factor IX activation, assayed by release of trichloroacetic acid-soluble ^{3}H-labeled activation peptide from purified [^{3}H]-factor IX, were similar when factor XIa was bound to platelets and when it was free in solution. The platelet-bound factor XIa was isolated by centrifugation through 20% sucrose and was functionally characterized both in a factor XIa coagulation assay and in the factor IX activation peptide release assay in comparison with unbound factor XIa in the presence of treated platelets. The functional activity of platelet-bound factor XIa as a factor IX activator as well as its structural integrity were shown to be fully retained on the platelet surface. Since platelets bind factor XI and promote its proteolytic activation to factor XIa, factor XIa binding to platelets may serve to localize factor IX activation to the hemostatic plug, where factor XIa is protected from inactivation by plasma protease inhibitors and where acceleration of subsequent coagulation reactions can occur.

PLATELETS participate in blood coagulation at various stages of the intrinsic system by interacting specifically with coagulation proteins and promoting the activation of factor XII,[1] factor XI,[1] factor X,[2] and prothrombin.[3,4] Previously we have demonstrated that the zymogen factor XI can interact specifically with the surface of activated platelets in the presence of the protein cofactor, high Mr kininogen, with which it associates in plasma as a noncovalent complex.[5] A consequence of this high-affinity, specific, saturable binding of factor XI to platelets is the proteolytic activation of factor XI in the presence of kallikrein by both factor XII–dependent and factor XII–independent mechanisms.[1] We have also shown that the enzyme, factor XIa, binds specifically to a site on activated human platelets distinct from that for factor XI.[6] Since an analysis of the factor XIa catalyzed activation of factor IX suggests that this is a kinetically favorable reaction,[7] we have now examined the interaction of factor XIa with platelets to determine the functional consequences on factor IX activation.

METHODS

Materials. All chemicals were the best grade commercially available and were purchased from Sigma Chemical Co, St. Louis, Mo; Fisher Chemical Co, Fairlawn, NJ; or J.T. Baker Chemical Co, Phillipsburg, NJ. Plasmas deficient in coagulation factors were purchased from George King Biomedical, Overland Park, Ka. Betaphase scintillation fluid was obtained from West Chem Products, San Diego, Calif. Carrier-free Na^{125}I and tritiated sodium borohydride (75 Ci/mmol) were purchased in crystalline form in sealed ampoules from New England Nuclear, Boston, Mass. Iodogen (1,3,4,6-tetrachloro-3, 6-diphenylglycouril) was obtained from Pierce Chemical Co, Rockford, Ill. Ultrol Hepes (N-2-hydroxyethylpiperazine N'-2-ethanesulfonic acid) was from Calbiochem-Behring Corp, La Jolla, Calif, and Sepharose 2B was from Pharmacia Fine Chemicals, Piscataway, NJ. The chromogenic substrate Pyr-Gly-Pro-Arg-paranitroanilide 2 HCl (S-2366) was a kind gift from AB KABI Peptide Research, Molndal, Sweden. Methyl silicon oil (1.0 DC200) and Hi Phenyl silicon oil (125 DC 550) were obtained from William F. Nye, Inc, Fairhaven, Mass.

Preparation of platelet suspensions. Platelet-rich plasma was obtained from citrated human blood as previously described.[8] Platelets were separated from plasma by gel filtration[6,9] into calcium-free, Hepes-buffered Tyrode's solution of the following composition: NaCl, 126 mmol/L; KCl, 2.7 mmol/L; $MgCl_2$ $6H_2O$, 0.98 mmol/L; NaH_2PO_4 H_2O, 0.376 mmol/L; Hepes, 15 mmol/L; dextrose, 5.6 mmol/L; bovine serum albumin, 0.35%; pH 7.4. Alternatively, platelets were washed by the procedure of Mustard et al[10] and were finally suspended in calcium-free, Hepes-buffered Tyrode's solution. Platelets were counted electronically using a Model ZBI Particle Counter (Coulter Electronics, Inc, Hialeah, Fla).

Purification of proteins. Factor XI was purified from 2 L of human plasma by a modification[11] of the method of Bouma and Griffin[12] as previously described.[7] The purified protein appeared homogeneous on polyacrylamide gel electrophoresis in the presence of SDS as previously published,[7] and had a specific activity of 270 U/mg protein. It was stored in 0.2 mol/L sodium acetate, 0.6 mol/L NaCl, pH 5.3 at −70 °C. Human high Mr kininogen was purified to apparent homogeneity and specific activity of 15 U/mg, and was converted to the two-chain, kinin-free form as previously described by Kerbiriou and Griffin.[13] Human factor IX was purified to a specific activity of 225 U/mg by a modification[7] of methods described by DiScipio et al[14] and by Miletich et al[15] and was a single band on SDS gel electrophoresis as previously published.[7] It was stored in 0.012 mol/L Tris, 0.045 mol/L glycine, pH 8.3 at −185 °C. Bovine two-chain factor XIIa was kindly provided by Dr E.P. Kirby of the Thrombosis Research Center, Temple University School of Medicine, Philadelphia, Pa, as a homogenous protein that hydrolyzed 3.78 × 10^9 mol of the chromogenic substrate S2302/min/μg protein at pH 8.0 and 37 °C. Human alpha-thrombin was a gift from Dr J.W. Fenton, II, New York State Department of Health, Albany, NY.

Preparation and characterization of factor XIa. Purified factor XI was activated by incubation at 37 °C with bovine factor XIIa as

previously described.[6] Maximal factor XIa coagulant activity appeared at two hours at which time 95% of the protein was present in cleavage products of Mr 48,000 and 32,000 as previously published.[6] The factor XIa was assayed for amidolytic activity (127 U/mL), coagulant activity (135 U/mL), and by immunoradiometric assay (750 μg/mL) as previously described[16] and was thereby determined to have a specific activity of approximately 170 to 180 U/mg protein.

Radiolabeling of proteins. Factor XI was labeled with ^{125}I utilizing the Iodogen method.[17] Most of the free ^{125}I was removed from the labeled protein by passage over a 1 mL G-25 column[18] and the protein was then dialyzed further in the presence of ovalbumin (1 mg/mL) to remove residual ^{125}I. The factor XI was then converted to factor XIa as described above, was shown to retain >85% of its coagulant activity and had a specific radioactivity of 1117 CPM/ng protein. In binding assays, when the proportion of unlabeled to radiolabeled factor XIa was varied with a constant final concentration of total factor XIa, a linear relationship was observed between the percentage of ^{125}I-labeled factor XIa in the mixtures and the amount bound.[6] This indicates that the affinities of the radiolabeled and unlabeled factor XIa were comparable. Factor IX was labeled with tritium by a modification of the method described by Van Lenten and Ashwell[19] and adapted for bovine factor X by Silverberg et al[20] as previously described.[7] The labeled protein was finally purified by alkaline gel electrophoresis,[21] appeared homogeneous as judged by SDS gel electrophoresis and fluorography[22] as previously reported,[7] and >99% of the radioactivity was precipitable in 5% trichloroacetic acid. The tritiated factor IX had a specific radioactivity of 475 CPM/ng and retained >90% of its coagulant activity compared with unlabeled factor IX.

Coagulation assays. Factors IX and XI and high Mr kininogen were assayed utilizing minor modifications of the kaolin-activated partial thromboplastin time[23] using appropriate congenitally deficient substrate plasmas, and results were quantitated on double logarithmic plots of clotting times versus concentration of pooled normal plasma. Factor XIa was measured utilizing a similar assay carried out in polystyrene tubes without the addition of kaolin. The quantitation of factor XIa activity was accomplished by means of a standard curve of the logarithm of clotting time versus the logarithm of the concentration of purified factor XIa.

Radiometric assay of factor IX activation. The release of trichloroacetic acid (TCA)–soluble ^{3}H-labeled activation peptide from (sialyl-^{3}H)-factor IX was measured as previously described.[7] Briefly, assays were carried out in Tris (50 mmol/L), NaCl (100 mmol/L), pH 7.5 (Tris buffered saline or TBS), containing bovine serum albumin (1 mg/mL) in reaction volumes of 300 to 500 μL. At given times of incubation of factor XIa with (sialyl-^{3}H)-factor IX in the presence of 5 mmol/L $CaCl_2$ at 37 °C, 80 μL samples were removed and added to 240 μL of an ice-cold mixture containing one part TBS and two parts 50 mmol/L EDTA, pH 7.5. To this mixture was added 160 μL of ice-cold 15% TCA or TBS, and following vigorous vortexing for 2 minutes it was centrifuged at 10,000 g for 3 minutes in a bench top Brinkman Model 3200 Microfuge (Brinkman Instruments, Inc, Westbury, NY). Aliquots (100 μL) of the supernatants were removed into 10 mL of scintillation fluid and counted in triplicate in a Beckman LS 8000 scintillation counter (Beckman Instruments, Inc, Fullerton, Calif).

Binding studies. Determinations of binding of factor XIa to platelets were carried out as previously described.[6] Briefly, 100 μL of gel-filtered platelets (2 to 4 × 10^8/mL) in calcium-free, Hepes-buffered Tyrode's solution, pH 7.4, were incubated at 37 °C with reactants including ^{125}I-labeled factor XIa in a total volume of 115 μL. All incubations were carried out in duplicate, and results represent means of two determinations, which were always within 5% of one another. After specified incubation times, 100 μL aliquots were removed and centrifuged in a microfuge (Model B, Beckman Instruments, Inc, Cedar Grove, NJ) through a mixture of silicone oils (5 vol. DC550:1 vol DC 200) in microsediment tubes with narrow bore extended tips (Sarstedt, Inc, Princeton, NJ). The tips containing the sediments were amputated with wire cutters and the sediments and supernatants counted separately in a gamma counter (Model CG 4000; Intertechnique, Plaisir, France).

Protein analyses. Protein assays were carried out as described by Lowry et al[24] and were also determined by absorbance at 280 nm employing $E^{1\%}_{280}$ = 13.4 for factor XI.[25] and 7.01 for high Mr kininogen.[26] Polyacrylamide slab gel electrophoresis in SDS was done by the procedure of Laemmli.[27]

RESULTS

Binding of factor XIa to platelets. Previously we have demonstrated that factor XIa binds specifically to a site on activated human platelets distinct from that for factor XI. The requirements for binding include the presence of high Mr kininogen and a platelet agonist, such as thrombin. A series of five identical experiments was carried out to determine the number and affinity of specific binding sites for factor XIa on activated human platelets obtained from five separate donors (Figs 1 and 2). In these experiments, gel-filtered platelets were incubated with high Mr kininogen and thrombin in the presence of ^{125}I-labeled factor XIa added at various concentrations, and total binding was determined. Nonspecific binding was also measured at two or three concentrations of ^{125}I-labeled factor XIa in the presence of a 50-fold excess of unlabeled factor XIa compared with the highest concentration of ^{125}I-labeled factor XIa and was found to be nonsaturable; ie, it was a linear function of added ligand, and ranged between 10% and 20% of total binding. Specific binding was determined as the difference between total and nonspecific binding after a 4-minute incubation at

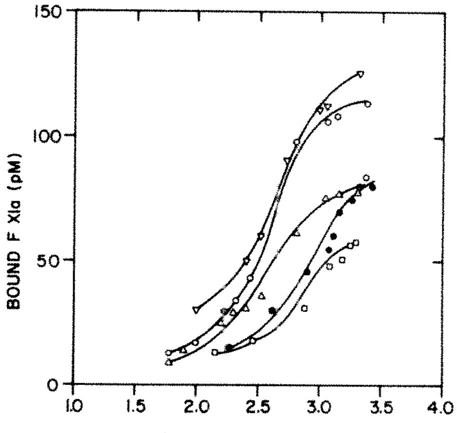

Fig 1. Specific binding of ^{125}I-factor XIa to platelets as a function of factor XIa concentration. Gel-filtered platelets at concentrations of 1.8 to 4.3 × 10^8/mL were incubated at 37 °C for 4 minutes within thrombin (0.25 U/mL), high Mr kininogen (12.5 μg/mL), and various concentrations of factor XIa. Nonspecific binding was measured in the presence of 14 μg/mL of unlabeled factor XIa and was subtracted from total binding to give specific binding. Results obtained in duplicate in five separate experiments with five separate donors are plotted as recommended by Klotz.[29]

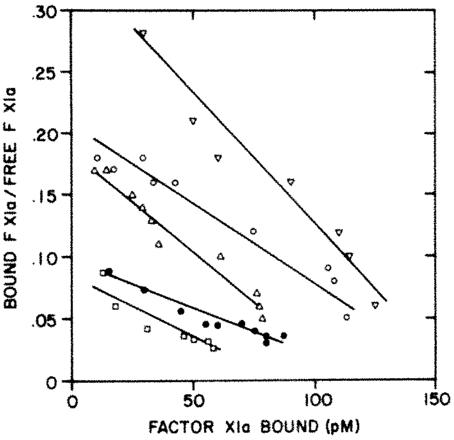

Fig 2. Scatchard plot of data presented in Fig 1.

which time it was demonstrated that specific binding had achieved a plateau and was more than 80% reversible.

To determine whether saturation had indeed been achieved under these experimental conditions, specific binding data for 5 separate experiments were plotted as recommended by Klotz[28] in Fig 1. This method of plotting ligand binding data has been suggested as means to determine whether or not a sufficient amount of ligand has been added in a binding experiment to approach saturation of binding sites. Thus, when the data are plotted as the amount bound versus the logarithm of the amount of ligand added, the result should describe a sigmoid curve, with the inflection point representing half-maximal binding, if saturation of binding sites has, in fact, been approached. The data plotted in Fig 1 suggests that approximately half the points represent data obtained at concentrations greater than those required to achieve half-saturation, and therefore should justify Scatchard analysis[29] provided equilibrium between bound and free ligand can be demonstrated.

The same data depicted in Fig 1 were then replotted according to the method of Scatchard[29] in Fig 2 to obtain estimates of the number and affinity of binding sites. The data suggest the presence of a single class of binding sites since a straight line can apparently be drawn through each set of binding data. Dissociation constants (Kd) calculated for each experiment gave a mean value of 822 pmol/L (range, 471 to 1250; SD, 312; SEM, 140) and the mean number of binding sites per platelet was 291 (range 196 to 489; SD, 137; SEM, 61).

Activation of factor IX by platelet-bound factor XIa. To examine directly the functional consequences of the binding of factor XIa to platelets, platelets with the bound enzyme were compared with factor XIa in solution in the presence of platelets under conditions not promoting factor XIa binding (Fig 3). Since binding of factor XIa to platelets requires platelet activation and the presence of the protein cofactor, high Mr kininogen,[6] platelets were incubated with factor XIa, high Mr kininogen, and thrombin to allow equilibrium binding of factor XIa to platelets. The coagulant activity of platelet-bound factor XIa was compared with that of unbound factor XIa in the presence of platelets previously treated with thrombin and high Mr kininogen. Gel filtered platelets were incubated with high Mr kininogen and thrombin in the presence or absence of ^{125}I-labeled factor XIa. Both samples were centrifuged through 20% sucrose, the platelets resuspended, and the amount of factor XIa bound was determined by the number of counts recovered in the pellet of the sample to which ^{125}I-factor XIa had been added. A control experiment carried out in the presence of a 50-fold excess of unlabeled factor XIa indicated that 80% of the binding was specific, whereas 20% was nonspecific. It was then confirmed by centrifugation through silicone oil that 65% of the factor XIa sedimented with platelets through sucrose remained bound to the platelets after resuspension. This sample was assayed for factor XIa activity in factor XI–deficient plasma without added kaolin. The clotting times obtained at three dilutions are plotted in Fig 3 *v* the amount of factor XIa determined by gamma counting to be present in the samples. To the other sample of platelets treated with high Mr kininogen and thrombin and centrifuged through sucrose was added ^{125}I-labeled factor XIa at the concentration (determined by gamma counting) depicted in Fig 3. It was confirmed by centrifugation of this sample through silicone oil that less than 4% of the added factor XIa was bound to the platelets. Since the clotting times were similar in the sample with mainly (65%) bound factor XIa and in the sample with mainly (96%) free factor XIa, it is concluded that the coagulant activity of factor XIa is fully retained (neither enhanced nor inhibited) when it is bound to the platelet surface.

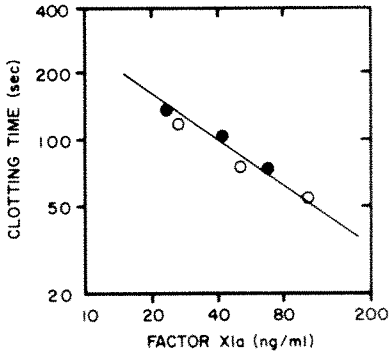

Fig 3. Factor XIa coagulant activity of platelet-bound factor XIa and unbound factor XIa in the presence of treated platelets. Gel-filtered platelets (2.0 × 10^8/mL) were incubated at 37 °C for 10 minutes in a total volume of 822 μL with high Mr kininogen (20 μg/mL) and thrombin (0.25 U/mL) in the presence or absence of ^{125}I-labeled factor XIa (3 μg/mL). The two samples were then centrifuged through 20% sucrose at 10,000 × g for 4 minutes and the pellets resuspended in 50 μL of Hepes-buffered Tyrode's solution with BSA (1 mg/mL) containing 50 μmol/L EDTA. The sample containing ^{125}I-labeled factor XIa (●) was counted in a gamma counter, found to contain the amount of factor XIa indicated, and was assayed at three dilutions for factor XIa coagulant activity as indicated in Methods. A similar amount of ^{125}I-factor Xa was added to the sample of treated platelets (○) which was also assayed for factor XIa coagulant activity.

The experiment presented in Fig 4 confirms this conclusion utilizing the radiopeptide release assay for factor IX activation. Gel-filtered platelets (4.5 × 10^8/mL) were incubated with high Mr kininogen (20 μg/mL) and thrombin (0.25 U/mL) in the presence of ^{125}I-labeled factor XIa (2.8

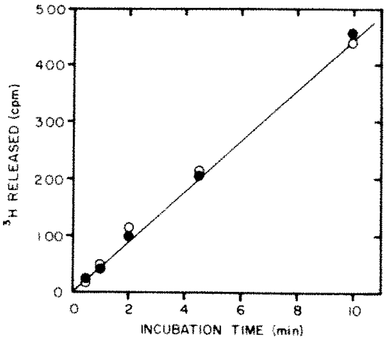

Fig 4. Effect of platelet-bound *v* free factor XIa on factor IX activation. Gel-filtered platelets (4.5 × 10^8/mL) were incubated for 8 minutes at 37 °C with high Mr kininogen (20 μg/mL), thrombin (0.25 U/mL), and factor XIa (2.8 μg/mL) or buffer. The two samples were then centrifuged through 20% sucrose and the pellets resuspended in 1 mL of calcium-free, Hepes-buffered Tyrode's solution. The amount of factor XIa bound to the platelets in the first sample (●) was determined as indicated in Results to be 132 ng/mL (8.25 × 10^{-10} mol/L), and an equivalent amount of factor XIa was added to the treated platelet sample (○). To each sample was added [sialyl-^{3}H] factor XI (2 μg/mL or 3.5 × 10^{-8} mol/L) and $CaCl_2$ (5 mmol/L). After the incubation times indicated, aliquots of the incubation mixtures were sampled for measurement of TCA-soluble ^{3}H release as indicated in Methods.

μg/mL). After an eight-minute incubation at 37 °C to allow binding of factor XIa to platelets, the amount bound was determined, after centrifugation through 20% sucrose, to be 4.7% of the amount added, ie, 132 ng/mL (8.25 × 10^{-10} mol/L) or 29 ng/10^8 platelets, of which 78% was specifically bound; ie, 22% of the binding was nonspecific as shown by a control experiment with a 50-fold excess of unlabeled factor XIa. Then, in a separate tube, unlabeled factor XIa or buffer was incubated with platelets, high Mr kininogen, and thrombin as indicated in the legend to Fig 4, the platelets sedimented through 20% sucrose and resuspended in Hepes-buffered Tyrodes solution. To the sample of platelets treated without factor XIa was added an amount of factor XIa equivalent to that bound to the platelets treated with factor XIa, ie, 132 ng/mL. It was confirmed in a separate incubation that 72% of the bound factor XIa remained bound whereas only 3.5% of the factor XIa was bound to the treated platelets. To the two samples containing mainly bound factor XIa and mainly unbound factor XIa, [sialyl-^{3}H]-factor IX and $CaCl_2$ were added for determination of factor IX activation by the peptide release assay. The results (Fig 4) confirm those of the experiment in Fig 3 and demonstrate that the activity of factor XIa as a factor IX activator is fully retained (neither enhanced nor inhibited) when it is bound to the platelet surface.

DISCUSSION

The experiments reported here confirm and extend our previous observation[6] that activated platelets interact specifically with the enzyme, factor XIa, which binds reversibly to high affinity sites distinct from those for the zymogen, factor XI.[5] A cofactor required for the binding of factor XIa to platelets is high Mr kininogen, which is also required for factor XI binding to platelets.[5,6] However, whereas both factor XI and high Mr kininogen are bound to activated platelets in the presence of physiologic concentrations of Zn^{2+} (25 to 50 μmol/L) and Ca^{2+} (2 mmol/L) ions,[32] factor XIa binding occurs in the absence of Zn^{2+} and Ca^{2+} ions or in the presence of EDTA, conditions which preclude the binding of high Mr kininogen.[6] Therefore the mechanism by which high Mr kininogen promotes factor XIa binding to activated platelets in the absence of Zn^{2+} and Ca^{2+} ions is not likely to involve coordinate binding of high Mr kininogen with factor XIa. This suggests that, whereas factor XI and high Mr kininogen may bind to platelets as a complex, similar to the coordinate binding to platelets of the complex of factor Xa and factor Va,[4] the platelet binding site for factor XIa is not likely to be plasma high Mr kininogen. The possible role in factor XIa binding of platelet high Mr kininogen, which appears to be stored in and secreted from platelet alpha-granules,[33] remains to be investigated.

Specific binding at saturation of factor XIa to thrombin-activated platelets in the presence of high Mr kininogen varied over a 3.7-fold range when platelets from five separate donors were employed (Figs 1 and 2). That this binding was, in fact, saturable is substantiated by analysis of the binding data according to the method of Klotz,[28] as shown in Fig 1. The partially dissociable nature of binding at later times of incubation of factor XIa with platelets initially[6] made us reluctant to derive binding constants by Scatchard analysis.[29] However, we have now carried out binding measurements at early time points when the majority of factor XIa binding is reversible, and subjected the data to Scatchard analysis, assuming equilibrium between free and bound ligand (Fig 2). The derived binding constants are in general agreement with our previously published conclusions[6] and indicate the presence of 130 to 500 factor XIa binding sites per platelet with a mean of 291 sites per platelet and a dissociation constant (Kd) of 822 pmol/L ± 140 (SEM).

The primary focus of the present study is to characterize the bound factor XIa functionally, having previously characterized it structurally and found it to be indistinguishable from unbound factor XIa; ie, a 160,000 Mr protein by SDS gel electrophoresis, consisting of a 50,000 Mr heavy chain and a 30,000 Mr light chain on reduced gels.[6] These data provided evidence that the bound protein was factor XIa and not a contaminant and no evidence for high molecular weight covalent complex formation with a platelet membrane component or for proteolytic degradation of the bound ligand. To study the coagulant activity of the platelet-bound ligand, we have employed an assay procedure and an experimental protocol that permit a direct and unequivocal functional characterization of factor XIa bound to the platelet surface. The activation peptide release assay for factor IX activation is highly specific since it monitors a physical property of the molecule that correlates well with the development of factor IXa coagulant activity and with the enzymatic activity of added factor XIa measured either by chromogenic or coagulation assays.[7] Using this method to assay factor XIa we have shown in experiments not reported here that rates of factor IX activation are similar in the presence and absence of platelets and whether factor XIa is bound to platelets or not. Since less than 10% of the total amount of added factor XIa is bound to platelets in the presence of thrombin and high Mr kininogen at saturating concentrations of added ligand, it was important to measure factor IX activation by bound and by free factor XIa. We therefore isolated the platelet-factor XIa complex by centrifugation through 20% sucrose and demonstrated using a coagulation assay (Fig 3) and the activation peptide release assay (Fig 4) that the functional activity of platelet-bound factor XIa is identical to that of unbound factor XIa. In these experiments it was demonstrated that approximately 80% of the platelet-bound factor XIa was specifically bound. The present observations allow us to conclude that both the functional activity and the structural integrity of factor XIa are fully retained on the platelet surface under our experimental conditions.

It has previously been demonstrated that phospholipids can accelerate the rate of bovine factor IX activation by surface-bound factor XIa.[34] In these experiments factor IX activation was measured by a factor IXa clotting assay and by proteolytic cleavage of factor IX in glass tubes containing surface-bound factor XIa. Rates of activation were increased 2- to 3-fold in the presence of phospholipids. The relationship between these findings and our present results is not clear. It should be emphasized that our studies were carried out with highly purified coagulation proteins. It is possible that a cofactor present in normal plasma cound influence rates of factor IX activation by factor XIa, but to our knowledge no direct evidence to support such a possibility is available.

Previously we have reported experiments, utilizing crude preparations containing factor XIa activity and plasma protease inhibitor activity, that platelets appear to protect factor XIa from inactivation by proteinases.[2] We were therefore interested to determine, using highly purified proteins, whether platelet-bound factor XIa is protected from inactivation by alpha-1-protease inhibitor, which has been reported to account for 68% of the factor XIa inhibitory activity in human plasma.[35] The results of our experiments (manuscript in preparation) confirm the hypothesis that platelet-bound factor XIa is indeed protected from inactivation in the presence of alpha-1-protease inhibitor.

The interpretation of the present studies in the context of what is known about the role of platelets in coagulation reactions is a matter of conjecture. Platelets bind factor XI tightly and specifically[5] and accelerate the rate of factor XI activation in the presence of factor XIIa or kallikrein.[1] Factor XIa also binds tightly and specifically to a site on the activated platelet surface distinct from the binding site for factor XI.[6] These interactions therefore can be viewed as localizing the activation of factor XI and the activity of factor XIa to the hemostatic plug where coagulation enzymes including factor XIa and factor Xa are protected from inactivation by plasma proteinase inhibitors.[2,36,37] The present studies indicate that the functional activity and structural integrity[6] of factor XIa are fully retained when the protein is bound to platelets. Kinetic analysis of the factor-XIa–catalyzed activation of factor IX (Km = 0.49 μmol/L; kcat = 7.7/s) suggests that this is a physiologically significant reaction.[7] Since the present studies indicate that the reaction rates are similar when factor XIa is bound to platelets and when it is free in solution, we suggest that factor IX activation by platelet-bound factor XIa is also a kinetically favorable reaction. Furthermore the reaction may occur preferentially on the platelet surface where factor XI is bound and activated, where factor XIa is tightly bound and may saturate binding sites when 5% to 10% of the factor XI in plasma is converted to factor XIa,[6] and where factor XIa, as well as factor Xa, can be protected from inactivation by protease inhibitors. Thereafter rates of factor X activation[2] and prothrombin activation[3,4] are greatly accelerated by accessory factors on the platelet surface, consistent with the amplifier effect of coagulation reactions implicit in the cascade[38] or waterfall[39] theory of coagulation as originally presented.

ACKNOWLEDGMENT

The authors are grateful to Dr Linda C. Knight and Monica Kollman for their assistance in radiolabeling proteins, to Dr Edward P. Kirby for providing bovine factor XIIa, and to Patricia Pileggi for typing the manuscript.

Effects of 2,3-Diphosphoglycerate on the Mechanical Properties of Erythrocyte Membrane

By Richard E. Waugh

Investigation by Schindler et al[1] and Sheetz and Casaly[2] have indicated that high (~10 mmol/L) concentrations of 2,3-diphosphoglycerate (2,3-DPG) have a destabilizing effect on erythrocyte membrane and the membrane skeleton. We have investigated changes in the membrane mechanical properties that occur at elevated 2,3-DPG levels in both intact cells and ghosts. The membrane shear modulus, viscoelastic recovery time constant, critical force, "plastic" viscosity, and material relaxation time constant were measured by standard micropipette and flow channel techniques. Intact cells showed no change in properties at physiologic ionic strength and 2,3-DPG concentrations of about 20 mmol/L, except for an increase in membrane viscosity resulting from an increased cellular hemoglobin concentration that occurs when the 2,3-DPG concentration is elevated. At ionic strengths 20% below physiologic and 2,3-DPG concentrations of ~20 mmol/L, decreases in membrane shear modulus and membrane viscosity were observed. In ghosts, no changes in these properties were observed at a 2,3-DPG concentration of 10 mmol/L and ionic strengths as low as 25% below physiologic, but a decrease in the force required to form tethers (critical force) was observed at physiologic ionic strength. The decrease in membrane shear modulus and viscosity of intact cells and the reduced critical force in ghosts are consistent with the results of other investigators. However, the difference in the effects of 2,3-DPG on ghosts and intact cells indicates that the effects of 2,3-DPG depend strongly on the conditions of the experiment. It appears unlikely that 2,3-DPG affects erythrocyte membrane material properties under physiologic conditions.

THE erythrocyte membrane consists of a phospholipid bilayer containing many integral proteins, an extracellular glycocalyx, and a membrane-associated proteinaceous skeleton at the cytoplasmic surface of the bilayer. Mechanically, it is recognized that the bilayer behaves like a two-dimensional liquid. It resists changes in area elastically, but it can freely undergo constant area shear deformation (in-plane deformation), and particles in the bilayer are free to diffuse in the plane of the surface. The shear elasticity that the membrane exhibits is due to the presence of the membrane skeleton, which also acts to limit the rate at which some integral proteins diffuse in the surface. Recently, it was observed that the lateral mobility of integral membrane proteins was increased in erythrocyte ghosts containing elevated levels of 2,3-diphosphoglycerate (2,3-DPG) and adenosine triphosphate (ATP).[1] Subsequently, Sheetz and Casaly[2] observed that polyanions, notably 2,3-DPG and ATP, accelerated the rate at which isolated membrane skeletons dissociate in vitro. The dissociative effects of 2,3-DPG were found to be much stronger than the effect of ATP on the isolated skeleton, 2,3-DPG having a half maximal effect at 2.5 mmol/L and ATP having a half maximal effect at 8.0 mmol/L. These results supported the hypothesis that the increased mobility of integral proteins was due to a decrease in the stability of the cytoskeleton, or an increase in the rate of exchange of the associations among the membrane skeletal components. Because of the importance of the skeleton in maintaining proper mechanical function of the membrane, it was postulated that 2,3-DPG might also affect the mechanical properties of the membrane. This postulate was supported by the observations of Chasis et al.[3] that ghosts with elevated 2,3-DPG concentrations fragmented more readily than control ghosts in the ektacytometer. It was suggested that these effects might serve an important physiologic function.

To test the effects of elevated concentrations of 2,3-DPG on the mechanical properties of erythrocyte membrane we have measured the intrinsic membrane material constants that have been defined to characterize the membrane mechanical behavior. We have performed these measurements on the membranes of both intact cells and resealed erythrocyte ghosts. The particular material constants that were measured are described and defined in the following section.

Definition of Material Properties

The mechanical behavior of the red cell membrane is complex. (For reviews see Evans and Hochmuth[4] and Evans and Skalak.[5]) Different constitutive relationships have been used to describe the material behavior, depending on the magnitude and duration of the applied forces. The resistance of the membrane to area changes is large, and the area of the membrane of each cell can be presumed to be constant during these experiments. The membrane resists in-plane extensions elastically. The maximum shear resultant in the surface, T_s, is related to the material extension ratio, λ, by the surface elastic shear modulus, μ[4]:

$$T_s = \frac{\mu}{2}(\lambda^2 - \lambda^{-2}) \qquad (1)$$

When surface deformations are dynamic, the membrane exhibits viscous character. For rapid deformations within the elastic regime, the total shear resultant can be written as the

sum of the elastic and viscous contributions[4]:

$$\mathrm{T}_s = \frac{\mu}{2}(\lambda^2 - \lambda^{-2}) + 2\eta\,\mathrm{V}_s \qquad (2)$$

where η is defined as the membrane viscosity coefficient for rapid deformation and V_s is the rate of surface shear deformation.

When the membrane is forced to maintain a deformed geometry for a long time, the stresses in the membrane relax, and the surface begins to assume a new "equilibrium" geometry.[6] The partial derivative of the log of the material extension with time is given by:

$$\frac{\partial \ln \lambda}{\partial t} = \frac{1}{2}\frac{\partial \tilde{\mathrm{T}}_s}{\partial t}[\tilde{\mathrm{T}}_s^2 + 1]^{-1/2} + \frac{\tilde{\mathrm{T}}_s}{2\tau_c} \qquad (3)$$

where the dimensionless shear resultant $\tilde{\mathrm{T}}_s$ is the ratio T_s/μ, the characteristic time τ_c is the ratio of η_c/μ, and t is time. The creep viscosity coefficient η_c characterizes the rate at which the material stresses relax.

In the flow channel experiment, cells that have adhered to a glass surface are subjected to a fluid shear force.[7] If the force is large enough a strand of membrane (tether) is pulled from the cell body. The force at which tethers begin to form is called the critical force. Originally[8] the critical force was thought to be related to the yield shear resultant of the membrane skeleton. However, recent evidence obtained in our laboratory indicates that tethers may not contain membrane skeleton. These observations support a view that tether formation involves stripping bilayer away from the skeleton. Therefore, the present results are reported in terms of the critical force, and not a yield shear resultant. Regardless of the molecular mechanism involved, the critical force provides a measure of membrane stability and resistance to fragmentation.

The rate at which the tether forms under forces exceeding the critical force is characterized by a viscosity coefficient.[8] For historical reasons we will refer to this as the plastic viscosity of the membrane, even though tether formation may not actually involve plastic deformation of the membrane.

MATERIALS AND METHODS

Intact cells

Cells were obtained from healthy donors either on the morning of an experiment or on the evening before and kept in acid citrate dextrose plasma prior to preparation for the experiment. Cells were separated from the plasma by centrifugation, the buffy coat was discarded, and cells were washed twice in isotonic phosphate buffered saline (PBS) (130 mmol/L NaCl, 25 mmol/L Na_2HPO_4, 6.2 mmol/L KH_2PO_4, 10 µmol/L sodium azide, pH 7.4). The osmolarity of the solutions was measured by freezing point depression and fell within range, 290 to 305 mOsm.

Elevation of the 2,3-DPG concentration was accomplished by the method of Duhm.[9] Packed cells (0.25 mL) were brought to a total volume of 5.0 mL in an incubating buffer containing 10.0 mmol/L inosine, 10.0 mmol/L pyruvate, 50 mmol/L Na_2HPO_4, and 79.5 mmol/L NaCl (300 mOsm, pH 7.4), and kept at 37 °C for two hours. To compensate for the decrease in internal pH due to the elevated concentration of impermeant anion after incubation, the cells were washed twice in phosphate buffered saline at high pH (pH 7.9 to 8.5) then suspended at high pH for measurement. Control cells underwent identical manipulations but were kept in PBS (pH 7.4) for the entire procedure. Cells not used for mechanical measurements were frozen at −70 °C until 2,3-DPG determinations could be made.

Sucrose incubation to deplete cations

In some control measurements, cells were preincubated in low ionic strength sucrose solutions to deplete cells of cations[10] and increase the MCHC under physiologic conditions. Cells were washed twice in PBS then suspended at 5% hematocrit at 37 °C for 40 minutes in a solution containing 5 mmol/L NaCl, 3.0 mmol/L HEPES (pH 7.4), and 240 mmol/L sucrose. The osmolarity of the solution was 300 mOsm. After 40 minutes cells were washed in PBS and suspended in PBS for measurements.

The concentration of 2,3-DPG within the cells was determined enzymatically (see Technical Bulletin No. 665. Sigma Chemical Co, St. Louis, Mo). All reagents were obtained from Sigma. Phosphoglycerate mutase was used to hydrolyse 2,3-DPG to 3-phosphoglycerate, and the amount of released phosphate was determined colorimetrically by the method of Fiske and Subbarow.[11]

The mean cellular hemoglobin concentration (MCHC) was determined by standard techniques. A suspension of red cells was sampled for hematocrit measurement using a capillary tube. An aliquot of the same suspension was taken for hemoglobin determination using Drabkin's solution and absorbance measurements at 540 nm.

Internal pH was determined by measuring the ratio of internal to external chloride concentrations. The method was identical to the one described by Knauf et al[12] with the exception that the cells were equilibrated at 37 °C rather than at 0 °C. ^{36}Cl was used to determine the amount of chloride inside and outside the cells. Cell water was determined by wet and dry weights and corrections for trapped water were obtained by using tritiated inulin as extracellular marker. Given the internal and external chloride concentrations, the hydrogen ion concentration ratio (hence the difference between the internal and external pH) can be calculated from the Donnan equilibrium condition:

$$\frac{[\mathrm{H}^+]_{out}}{[\mathrm{H}^+]_{in}} = \frac{[\mathrm{Cl}^-]_{in}}{[\mathrm{Cl}^-]_{out}} \qquad (4)$$

or

$$\mathrm{pH}_{in} - \mathrm{pH}_{out} = \log_{10}([\mathrm{Cl}^-]_{in}/[\mathrm{Cl}^-]_{out})$$

Ghost preparation

Resealed ghosts were prepared by a method similar to that of Schwoch and Passow.[13] Cells were drawn and washed on the afternoon before an experiment and refrigerated overnight in isotonic phosphate buffered saline. Cells were suspended at 50% hematocrit in 165 mmol/L NaCl and cooled to 0 °C. Thirty-five milliliters (35 mL) of lysing solution (3.5 mmol/L acetic acid, 4.0 mmol/L $MgSO_4$, 0.1 mmol/L phenyl-methyl-sulfonyl-flouride, and 1.0 mmol/L EGTA) were added to 3.5 mL of cell suspension. Care was taken to assure that the temperature remained at 0 °C (± 0.2 °C). After five minutes, 3.5 mL of resealing solution (2.0 mol/L KCl, 25 mmol/L TRIS) was added to the lysate. After five minutes at 0 °C the suspension was transferred to a 37 °C bath and incubated for 45 minutes. After incubation, the ghosts were washed in phosphate buffered saline (300 mOsm, pH 7.4, unless otherwise noted) and suspended in the same buffer for measurements. All mechanical measurements were performed at 37 ± 1 °C.

Measurement of material properties

The surface elastic shear modulus was measured by micropipette aspiration after the method of Evans and La Celle.[14] Cells were aspirated in the dimple region into a micropipette (0.9 to 1.2 μm, ID). The length of the projection in the pipette, L_p, was recorded as a function of the aspiration pressure, ΔP. Evans[15] showed that the relationship between L_p and ΔP is approximately linear when $L_p > R_p$. Chien et al[16] have used the following linear approximation to Evans' original formulation:

$$\frac{\Delta P\, R_p}{\mu} = C_1 \frac{L_p}{R_p} + C_2 \qquad (5)$$

where $C_1 = 2.45$, $C_2 = -0.63$, R_p is the pipette radius, and μ is the surface elastic shear modulus. The shear modulus was calculated from the measured data pairs (ΔP, L_p) by linear regression to Equation 5.

The viscosity coefficient for rapid deformation was measured by the whole cell recovery technique developed by Hochmuth et al.[17] Cells were allowed to settle onto a glass surface and adhere. The adhesion depended critically on the concentration of bovine serum albumin in the suspending medium. The concentration was adjusted in the range 1.0 to 4.0 mg/mL to obtain the desired "stickiness" between the cells and the glass. Cells attached at a single point were aspirated by micropipette at their free edge and extended to approximately twice their resting length by withdrawing the pipette. The cells were released suddenly and the time course of their recovery to their initial geometry was observed. The length-to-width ratio of the cells decreases exponentially with time[17] and can be described by the following relationship:

$$\frac{(L/W) - (L/W)_\infty}{(L/W) + (L/W)_\infty} \cdot \frac{(L/W)_m + (L/W)_\infty}{(L/W)_m - (L/W)_\infty} = e^{-t/\tau} \qquad (6)$$

where $(L/W)_m$ is the largest ratio of length to width and $(L/W)_\infty$ represents the length-to-width ratio in the completely relaxed state. The time constant, τ, is the ratio of the membrane viscosity coefficient to the membrane shear modulus: ($\tau = \eta/\mu$). The length and width of the cell were measured as functions of time, and the time constant was determined by nonlinear least squares regression with two free parameters, the time constant τ and the relaxed length-to-width ratio, $(L/W)_\infty$.

The cells were also tested using the flow channel technique.[7,18] A thin (0.015 mm × 1.0 cm × 4.0 cm) channel was formed with a parafin gasket between a slide and coverglass. The glass in the channel was pretreated with an 8.0% plasma solution. Cells were infused into the channel at a 1.5% to 2.0% hematocrit and allowed to settle on the surface of the channel and remain undisturbed for 30 minutes, during which time some of the cells became attached to the glass. A force was exerted on the cells by fluid moving through the channel. The flow was controlled by adjusting the pressure drop across the channel, and the pressure was monitored using a differential pressure transducer. The magnitude of the force was approximated by the product of the fluid shear stress at the wall times the projected area of the cell. To be consistent with previous flow channel studies,[7,18] a value of 50 μm^2 was used for the projected area of the cell. This corresponds to a disc approximately 8.0 μm in diameter. When the force becomes large enough, a strand of membrane (tether) begins to form between the body of the cell and the attachment site. The rate of tether formation was measured as a function of the applied force. Two parameters were determined from the data: the critical force f_c is the force at which tether growth began to occur, and the plastic viscosity coefficient η_p provides a measure of how fast the tether forms when f_c is exceeded.

The long-term membrane relaxation was measured using the method of Markle et al.[6] Cells were suspended at dilute concentration in phosphate buffered saline (pH 7.4, ~300 mOsm) containing a carefully measured concentration of bovine serum albumin. Cells were aspirated into micropipettes in the dimple region. After a shear modulus measurement was performed the cell was held at a fixed pressure for 20 minutes. Exposure of the cell to light was minimized. After 20 minutes the cell was expelled from the pipette. A residual bump remained on the cell surface. The height of the bump was constant for periods of several minutes after expulsion. The height of the bump was measured within 1 minute after expulsion, as soon as the cell could be recaptured and positioned in the field of view. The ratio of the height of the bump in the pipette before release, Z_0, to the height of the residual bump, Z, gives a measure of the material relaxation (creep) coefficient, η_c. The relationship between Z/Z_0 and time for different values of η_c is given by the solution to Equation 3[6] and is not available in closed form.

RESULTS

Intact Cells

Effects of inosine-pyruvate-phosphate (IPP) incubation. The incubation of intact erythrocytes in IPP caused a dramatic increase in the concentration of 2,3-DPG within the cells. Typically, concentrations increased from about 2.0 to 4.0 mmol/L in control cells to postincubation levels of 17.0 to 24.0 mmol/L. The concentration of chloride within the cells decreased during the incubation because of the increasing concentration of impermeant anion. This causes a decrease in intracellular pH (calculable from the Donnan equilibrium) and an increase in the mean cellular hemoglobin concentration (MCHC) due to the loss of water that accompanies the loss of chloride. To avoid artifactual results due to the effects of changes in intracellular pH, cells with elevated concentrations of 2,3-DPG were suspended in media with high external pH (7.9 to 8.5). The relevant data for solution osmolarity, MCHC, and intracellular pH are given in the tables summarizing the results of each mechanical test.

Shear modulus measurements. Three separate experiments are summarized in Table 1. Because of the strong dependence of the calculated value of the shear modulus on pipette radius and the uncertainty in measuring pipette diameters, valid comparisons between different cell populations can only be made within each experiment. Furthermore, because undetectable small particles lodged in the pipette tip during the experiments could change the effective radius of the pipette, measurements on control cells were performed at the beginning and the end of each experiment, and the average values were compared to ensure that the pipette had not been partially occluded during the course of the experiment. Any difference less than 10% in the value of μ measured at the beginning and end of an experiment was considered satisfactory. In fact, for the data shown in Table 1, the difference was less than 3.0%.

Because cells with elevated 2,3-DPG have higher than normal MCHCs, the first experiment was performed at hypotonic salt concentration. A significant difference was observed between the moduli of cells loaded with 2,3-DPG by incubation in inosine-pyruvate-phosphate and cells incubated in saline (controls); ($p(\mu_1 = \mu_2) = 0.0004$, *t* test). Note

Table 1. Shear Modulus of Intact Erythrocytes as a Function of 2,3-DPG Concentration

*Elevated by preincubation in sucrose.

that this experiment (Table 1, experiment 1) duplicated (as closely as possible) the conditions of the experiment 2 in Table 2.

The second experiment was performed to see if the decrease in shear modulus was due simply to the change in salt concentration. No difference in shear modulus was observed in control cells over the range of salt concentrations used in the experiments.

The third experiment was performed to test for changes in shear modulus with 2,3-DPG concentrations at physiologic ionic strength. The cells with elevated 2,3-DPG levels were compared to two different control populations: one with a normal MCHC and one with an MCHC that had been elevated by preincubation in low ionic strength sucrose solutions to deplete the cells of cations. The shear modulus for the 2,3-DPG loaded cells was not significantly different from either of the control populations.

In a fourth experiment (not listed in the table) the surface shear moduli of 2,3-DPG-loaded cells was found to be 0.0072 dyn/cm at 290 mOsm (15 cells, SD = 0.0014 dyn/cm) and 0.0054 dyn/cm at 220 mOsm (15 cells, SD = 0.0009 dyn/cm). These results are consistent with the results shown in Table 1, and indicate that the combination of elevated 2,3-DPG concentration and low salt concentration causes a reduction in the membrane shear modulus. The modulus for control cells at 290 mOsm was tested prior to the measurements on 2,3-DPG-loaded cells. The measured value was 0.0065 dyn/cm, SD = 0.0007, n = 10. Unfortunately, the pipette used in that experiment was lost before the last batch of control cells could be tested to check for partial occulsion of the pipette. Because of this, the results of this last experiment are inconclusive in themselves. Nonetheless, they are consistent with, and supportive of, the results given in Table 1.

Viscoelastic recovery. Measured values of the time constant for viscoelastic recovery for intact cells are tabulated in Table 2. Two experiments are summarized in the table. In experiment 1, cells with elevated 2,3-DPG concentrations are compared to control cells at physiologic salt concentration. The time constant for recovery is longer at elevated 2,3-DPG levels. Note that in experiment 1, the increase in external pH overcompensated for the decrease in internal pH brought about by the elevated 2,3-DPG concentration. To see if this overcompensation might have affected the recovery time, measurements were performed on control cells suspended in a buffer with pH 8.5. For the controls at pH 8.5, τ = 0.081s (SD = 0.030s, n = 15). This is not significantly different from the controls measured at pH 7.4 (P = 0.14). This indicates that the high pH was not the major factor causing the increased recovery time.

Table 2. Viscoelastic Recovery Time Constant for Intact Erythrocytes With Elevated 2,3-DPG Concentrations

Expt No	[2,3-DPG] (mmol/L)	Osmolarity (mOsm)	MCHC (g/dL)	pH_{in}	$\langle\tau\rangle$ (sec)	SD	n	P

2	19.1	242	36.9	7.2	0.065	0.036	17	0.98
	1.4	242	32.1	7.3	0.065	0.034	17	

During the course of our studies several papers appeared indicating that the recovery time constant for an erythrocyte was increased at high MCHC.[19,20] To check for the effects of increased MCHC in our measurements, experiment 2 was performed at reduced salt concentration to swell the cells and reduce the MCHC. Under these conditions no difference in the recovery time constant was observed between cells with elevated and normal 2,3-DPG concentrations.

Calculation of membrane viscosity. The membrane viscosity coefficient for rapid deformation is equal to the product of the recovery time constant and the membrane shear modulus. The coefficients calculated from the data in Tables 1 and 2 are given in Table 3. At physiologic salt concentrations there is an increase in the apparent membrane viscosity which is probably due to an increase in MCHC. At low salt concentration there is a reduction in membrane viscosity in proportion to the reduction in the membrane shear modulus. The data obtained from erythrocyte ghosts (see Tables 6 and 7) are also included for comparison.

Other viscosity coefficients. Because in our early experiments the viscosity coefficient for rapid deformation at physiologic ionic strength changed in the opposite direction

to what was expected, additional measurements of membrane properties were made. In the flow channel, strands of membrane (tethers) were formed from cells. No changes in either the critical force or the plastic viscosity coefficient were observed as a result of increasing intracellular 2,3-DPG levels (Table 4).

It should be noted that the results of the flow channel experiment can be affected by the extrinsic geometry of the cells. It is possible that real differences in the intrinsic membrane properties might have been masked by compensating differences in cell geometry between the two cell populations. Cells with high levels of 2,3-DPG tended to be more cupped than control cells, and their projected diameters when at rest in the channel were about 10% smaller than controls. (From the flow channel recordings, we estimated an average diameter of 8.5 μm for controls and 7.8 μm for 2,3-DPG loaded cells. These measurements are probably overestimates of the cell diameter because resolution was limited and measurements were made between outer edges of the diffraction band around the cells. This edge was chosen for measurement because it gave the best contrast and highest reproducibility.) It is not known how the difference in geometry would affect the experimental results because the cupped shape is expected to increase the fluid drag on the cell, whereas the smaller diameter is expected to decrease the drag on the cell. The fact that the cell geometries were similar (although not identical) and the lack of a detectable difference in the flow channel measurements indicate that 2,3-DPG does not significantly affect the "plastic" behavior of intact cells.

The last material parameter measured as a function of 2,3-DPG concentration in intact cells is the time constant for stress relaxation. Markle et al[6] have measured this quantity for normal cells and found it to be a strong function of the bovine serum albumin (BSA) concentration in the suspending medium. In the present experiments (Table 5), the BSA concentration was carefully controlled and constant, and the difference in the residual bump heights for cells with and without elevated 2,3 DPG concentrations was measured. No significant difference in the residual deformation was observed between the two cell populations.

Ghosts

Schindler et al[1] observed an increase in the lateral mobility of membrane proteins in erythrocyte ghosts at elevated 2,3-DPG concentrations. To test for possible changes in membrane material properties under the conditions of those experiments, we have measured the viscoelastic recovery time constant, the surface shear modulus, and the critical force for tether formation of erythrocyte ghosts, with and without 2,3-DPG added to the cells during lysis. The results of these measurements are summarized in Tables 6 through 8.

Table 5. Residual Deformation (Intact Cells)

[2,3-DPG] (mmol/L)				Z/Z_0			
Avg	SD	n	pH_{in}	Avg	SD	n	P
2.0	0.6	6	7.1–7.3	0.58	0.10	12	0.15
20.2	2.0	9	7.4–7.6	0.52	0.13	15	

Ghost morphology and size. Morphologically, the ghosts were nearly all discocytes although there were usually a few echinocytes and cups. The number of echinocytes and cups varied from preparation to preparation, but these nondiscoidal cells were not used for measurements. We estimated the area of cells in the flow channel by taking the product of the length and width of the cells at zero applied force multiplied by $\pi/4$. It should be recognized that because of limited resolution, these measurements are potentially subject to significant errors in absolute magnitude, but they should provide reliable comparisons for the resting diameters of the different cell populations. The projected area of the 2,3-DPG-loaded ghosts was 60.6 μ^2, SD = 10.1 μm^2, n = 107. The projected area of control ghosts was 63.3 μm^2, SD = 9.4 μm^2, n = 59. These were not significantly different by the student *t* test ($P = 0.08$). Precise measurements of cell thickness were not possible, but no obvious difference in the thickness dimensions of the different cell types was observed.

There was no appreciable change in the viscoelastic recovery time constant under the conditions of our measurements (Table 6). The salt concentration of the 16 mmol/L 2,3-DPG samples was elevated because these ghosts were visibly swollen after formation and the higher salt concentration was needed to return them to their normal biconcave shape. (Phosphate was added to two of the samples at the suggestion of Dr M. Sheetz, who pointed out that the accelerative effects of 2,3-DPG on cytoskeletal dissociation that he has observed[2] only occurred in the presence of phosphate.) These

10.0	0.70	0.24	25		0.00178	0.0017	25	

results are consistent with the results on intact cells at low ionic strength (Table 2) that 2,3-DPG does not affect the viscoelastic recovery time constant.

Unlike the results on intact cells (Table 1), there was no effect of 2,3-DPG (at a concentration of 10 mmol/L)* on the surface shear modulus of erythrocyte ghosts at either physiologic or reduced ionic strength (Table 7). However, there was a significant reduction in the force required to form tethers (Table 8). This is consistent with the observations of Chasis et al,[3] who observed an increase in the rate of fragmentation of 2,3-DPG loaded ghosts as measured in the ektacytometer. Once the threshold was exceeded, the rate at which the tethers formed was not affected by 2,3-DPG, as indicated by the viscosity coefficients shown in Table 8.

DISCUSSION

The observations of Schindler et al[1] on the lateral diffusion of intramembrane proteins and the data of Sheetz and Casaly[2] on the dissociation of erythrocyte membrane skeletons in vitro have provided strong evidence that a high concentration of 2,3-DPG is disruptive to the erythrocyte membrane skeleton. Because the membrane skeleton is the structural basis for the shear elasticity of the membrane and probably accounts for most of the membrane shear viscosity, changes in membrane material properties at elevated levels of 2,3-DPG were expected. Specifically, if a higher fraction of the skeletal proteins were to exist in a dissociated form, one would expect a decrease in membrane stability and possible reductions in the viscosity coefficients for viscoelastic recovery, tether formation, and creep. Consistent with these expectations, a reduction in shear modulus was observed in intact cells with elevated 2,3-DPG levels at subphysiologic salt concentrations, and a reduction in the critical force for tether formation was observed in resealed ghosts. The reduced surface shear modulus, coupled with observations that the viscoelastic recovery time constant did not change, indicate that the membrane viscosity coefficient for rapid deformation also is reduced at low salt concentration. However, no changes were detected in the surface shear modulus or the recovery time constant of ghosts, and no changes were detected in the critical force or the extent of residual deformation in intact cells. Furthermore, the reduction in shear modulus in intact cells was observed only at subphysiologic salt concentrations (240 mOsm) and did not occur under physiologic conditions.

These results demonstrate that lateral mobility is not simply related to the viscosity of the membrane composite as measured by the whole cell recovery experiments. We reach this conclusion in spite of the fact that the values of the membrane viscosity obtained by the two methods are quite similar. Koppel[21] calculated a value of 4.6 × 10^{-4} dyn s/cm from lateral mobility measurements in mouse erythrocytes. This is very close to the values for normal cells obtained in the present investigation (Table 3). This agreement appears to be coincidental. In erythrocyte ghosts, Schindler et al[1] found that the lateral mobility of integral proteins was increased by a factor of 2.5 when the concentration of 2,3-DPG was increased from near zero to 12.5 mmol/L. In contrast, no change in the membrane viscosity of erythrocyte ghosts was detected in the present study at concentrations of 2,3-DPG up to 16.0 mmol/L. The fractional reduction in membrane viscosity observed in intact cells at low ionic strength and elevated (~20 mmol/L) 2,3-DPG concentrations (Table 3, lines 1 and 3) is also significantly less than the fractional change in lateral mobility that Schindler et al[1] observed.

The reason for the discrepancy may be indicated by the results of the flow-channel experiments on ghosts. Preliminary immunochemical evidence obtained in our laboratory indicates that the tethers formed in the flow channel do not contain appreciable amounts of spectrin. That is, it appears that tethers consist primarily of a membrane bilayer that has been separated from the skeletal matrix. If this is so, the ease with which tethers form should depend on the "tightness" of the association between the bilayer and the membrane skeleton. The decrease in critical force that we have observed in ghosts may be indicative of a weakening of the skeletal-bilayer association and could account for the large increase in lateral mobility that has been observed. Weakening of the bilayer-skeletal interaction could also account for the increased rate of fragmentation of ghosts containing 2,3-DPG (10 mmol/L) that has been observed in the ektacytometer.[3]

The effects of 2,3-DPG on the mechanical properties of intact erythrocytes under physiologic conditions appear to be minimal. The increase in membrane viscosity that we have observed is opposite to the behavior one would predict on the basis of the observations of Schindler et al,[1] who measured an increase in the rate of lateral diffusion of membrane proteins at high concentrations of 2,3-DPG. (Increased rate of diffusion should correspond to decreased viscosity and more rapid viscoelastic recovery.) This result is almost certainly due to the increase in MCHC that occurs with increased 2,3-DPG concentrations and not due to the direct influence of 2,3-

---

*This concentration was chosen because the increased fragmentation rate of ghosts in the ektacytometer observed by Chasis et al[3] was near-maximal at 10 mmol/L 2,3-DPG.

DPG. Two other laboratories have shown that high cellular hemoglobin concentration increases the viscoelastic recovery time constant of intact erythrocytes.[19,20] The MCHCs in the present experiment are as high as the highest MCHCs in those studies. It is possible that the high MCHC in our experiments is masking a decrease in membrane viscosity caused by the elevated 2,3-DPG concentrations. Because of this, the change in membrane properties that we have measured at subphysiologic salt concentrations may be a more accurate reflection of the direct effects of 2,3-DPG on the membrane. It is surprising, however, that no effect of 2,3-DPG on the viscoelastic properties of ghost membranes was observed at any salt concentration.

A disturbing feature of the present results is the dissimilarity of the effects of 2,3-DPG on intact cells and ghosts. With the exception of the shorter recovery time constants for ghosts (indicative of lower membrane viscosity), the properties of the control ghosts were indistinguishable from the properties of the intact cells. However, none of the effects of 2,3-DPG on intact cells were observed in ghosts and vice versa. This indicates that the effects of 2,3-DPG depend strongly on the conditions of the experiment, and it emphasizes the danger of extrapolating results obtained in one membrane system to another.

The present observation of a change in the membrane shear modulus in intact cells at "low" salt concentration suggests that there is a cooperative effect of high 2,3-DPG concentration and low ionic strength on the membrane properties. Such a cooperative effect could account, in part, for the dissimilar results obtained in the different membrane systems. The reduction of the shear modulus in intact cells was observed at a 2,3-DPG concentration of about 20 mmol/L and a salt concentration of about 240 mOsm. The concentration of 2,3-DPG in the ghost experiments (10 mmol/L) may have been insufficient to produce similar effects at the experimental salt concentration (225 mOsm). It is important to note that the changes in lateral mobility that were observed occurred at salt concentrations below 140 mOsm,[1] and it is possible that changes in the membrane shear modulus of ghosts might occur under those conditions. On the other hand, the change in lateral mobility could be due to a completely separate effect, as indicated by the reduction in the critical force of 2,3-DPG loaded ghosts at physiologic salt concentrations.

The present results confirm the observations of early investigators that under some conditions 2,3-DPG acts to destabilize erythrocyte membrane. Our observations that the effects do not occur under physiologic conditions indicate that the effects of 2,3-DPG in erythrocytes are not physiologically important. However, the recent discovery of spectrinlike and ankyrinlike molecules in a variety of cell types raises the possibility that dissociative effects of 2,3-DPG could have importance in cytoskeletal regulation in other cells. The fact that the effects of 2,3-DPG are most evident in erythrocytes when the MCHC is low or in the absence of hemoglobin (in ghosts) suggests that the effect may be more important in cell types other than erythrocytes. Although the mechanism by which 2,3-DPG achieves its effect is not known, our observations suggest that it could play a role in regulating the interaction between membrane and cytoskeletal elements.

ACKNOWLEDGMENT

The author gratefully acknowledges Michael Sheetz for his suggestions, encouragement, and advice during this project and for making his data available prior to publication; Dr Philip Knauf for his advice and assistance regarding changes in intracellular pH and the measurement of chloride ratios to determine the change in intracellular pH; and Dr N. Mohandas for making his data available prior to publication. The author also acknowledges the technical assistance of George Mazzeo, Nancy Mann, and Donna Brooks.

The Effect of $\overline{\mathrm{C1}}$ Inhibitor Upon Hageman Factor Autoactivation

By Rachelle Weiss, Michael Silverberg, and Allen P. Kaplan

Using components purified from human plasma, we have examined the effects of $\overline{\mathrm{C1}}$ Inhibitor ($\overline{\mathrm{C1}}$ INH), the primary inhibitor of activated Hageman Factor (HFa) and Hageman factor fragment (HFf), on Hageman Factor (HF) autoactivation. When Hageman factor was exposed to a negatively charged surface, provided by either a glass cuvette or dextran sulfate, the addition of $\overline{\mathrm{C1}}$ INH gave a dose-dependent inhibition of the activity observed. The ability of $\overline{\mathrm{C1}}$ INH to decrease the maximal enzymatic activity generated was markedly temperature dependent with inhibition increasing as the temperature was raised from 4 °C to 37 °C. Although the rates of both autoactivation and inhibition were decreased at lower temperatures (4 °C), the latter rate was more sensitive to temperature modulation. When HF (final concentration 1 μmol/L) was incubated with C1 INH (0.54, 1.07, and 2.14 μmol/L) in the absence of an initiating surface, no increases in enzymatic activity were observed for up to 48 hours regardless of the $\overline{\mathrm{C1}}$ INH concentration. However, SDS polyacrylamide gel electrophoresis of the incubation mixture revealed that HF autodigestion had occurred by 48 hours despite the presence of C1 INH. In addition, the appearance of a new band suggested that a complex had been formed between the inhibitor and activated HF. Our findings indicate that $\overline{\mathrm{C1}}$ INH does not prevent HF autoactivation but rather inactivates the products of HF autodigestion.

© 1986 by Grune & Stratton, Inc.

When human Hageman factor (HF) is activated it converts prekallikrein to kallikrein[1] and Factor XI to Factor XIa[2] to initiate kinin formation and intrinsic coagulation. The main control mechanism for these reactions is the inhibition of activated Hageman Factor (HFa)[3] and Hageman factor fragments (HFf)[4] by $\overline{\mathrm{C1}}$ Inhibitor ($\overline{\mathrm{C1}}$ INH). The mechanism by which human Hageman factor becomes activated initially appears to involve autoactivation[5-7] as well as cleavage by plasma kallikrein[8]; in prekallikrein deficient plasma,[9] autoactivation may be the primary mechanism[10] although normal reciprocal activation of prekallikrein and Hageman factor[7] is much faster.

Since autoactivation is a reaction in which activated Hageman factor (HFa) digests native Hageman factor[5] to form more active enzyme, one might predict that $\overline{\mathrm{C1}}$ INH would inhibit this process by inactivating HFa. However, it is also possible that $\overline{\mathrm{C1}}$ INH interacts with native Hageman factor to inhibit cleavage and, thus, autoactivation. Such a mechanism has been reported for the ability of $\overline{\mathrm{C1}}$ INH to inhibit autoactivation of native $\overline{\mathrm{C1}}$,[11] even though they do not form a demonstrable complex in plasma. This occurs in addition to the known ability of $\overline{\mathrm{C1}}$ INH to inactivate $\overline{\mathrm{C1r}}$ and $\overline{\mathrm{C1s}}$.[12] We have sought to distinguish between these two possible effects upon Hageman factor autoactivation. Our data demonstrate for the first time that $\overline{\mathrm{C1}}$ INH impedes HF autoactivation when it is assessed functionally. It appears to do so by inhibiting the resultant HFa but no demonstrable interaction with HF to prevent its cleavage was observed.

MATERIALS AND METHODS

Reagents were obtained as follows: dextran sulfate (M_r 500,000) and diisopropylfluorophosphate (DFP; Sigma Chemical Co, St. Louis, Mo); N-benzoyl-L-isoleucyl-L-glutamyl-glycyl-L-arginine-pNA (S2222) (Kabi, obtained from Helena Laboratories, Beaumont, Tex); and phenylalanine-phenylalanine-arginine-CMK (Calbiochem-Behring, San Diego, Calif).

Hageman factor (HF) was purified from human plasma using previously published protocols[5,13] and stored at −60 ° in the presence of 10 mmol/L benzamidine. It had activity equivalent to the presence of 1.3% active enzyme. $\overline{\mathrm{C1}}$ Inhibitor ($\overline{\mathrm{C1}}$ INH) was a gift from Dr Peter Harpel, Cornell Medical School, New York, NY. It was also purified from human plasma following the method of Harpel[14] and both preparations were utilized in each experiment with similar results. To minimize any traces of amidolytic activity against S2222 present in the $\overline{\mathrm{C1}}$ INH preparation, it was incubated with 10 mmol/L DFP for one hour followed by extensive dialysis. Prior to use, proteins were dialyzed into 0.1 mol/L sodium phosphate buffer pH 7.0 containing 0.001% Triton X-100.[15] Protein concentrations were determined by the method of Lowry et al[16] using human IgG as a standard.

Amidolytic activity was determined by introducing 5 μL of enzyme into 400 μL of chromogenic substrate S2222 at a final concentration of 0.5 mmol/L in 0.05 mol/L Tris-HCl, 0.001% Triton X-100, pH 7.8, in plastic cuvettes (Walter Sarstedt Inc, Princeton, NJ). The absorbance change at 405 nm was recorded using either a Beckman DU-8 spectrophotometer or a Gilford Model 250 recording spectrophotometer connected to an Apple IIe computer to facilitate data analysis.

Autoactivation in glass cuvettes. Glass cuvettes were cleaned with nitric acid and exhaustively rinsed with distilled water prior to use (Fig 1). In these experiments it was necessary to inhibit any activated Hageman factor (HFa) present in the HF preparation. HF (4.8 μmol/L) was preincubated with 5 μmol/L Phe-phe-arg-CMK for 20 minutes. The final concentration of HF within the cuvettes was 4.3 μg/mL (54 nmol/L), while that of $\overline{\mathrm{C1}}$ INH was either 221 or 110.5 μg/mL (2.1 or 1.05 μmol/L, respectively). Absorbance at 405 nmol/L was continuously recorded for seven hours.

Autoactivation in polypropylene tubes. HF (final concentration 1 μmol/L) was incubated in polypropylene tubes in the presence or absence of C1 INH (2.14, 1.07, and 0.54 μmol/L for up to 48 hours at 37 °C.) Five μL samples were tested for amidolytic activity at 8, 24, 30, and 48 hours. HF was not preinhibited.

Activation in the presence of dextran sulfate (DS). DS 50 μg/mL in 20 mmol/L sodium phosphate buffer pH 7.5 containing 0.001% Triton X-100 was freshly prepared prior to each experiment. HF (final concentration 1 μmol/L) was incubated with DS (final concentration 5 μg/mL) in the presence or absence of $\overline{\mathrm{C1}}$ INH (2.14, 1.07, and 0.54 μmol/L) in polypropylene tubes for up to 24 hours at each of three temperatures (4 °C, 25 °C, and 37 °C). At selected

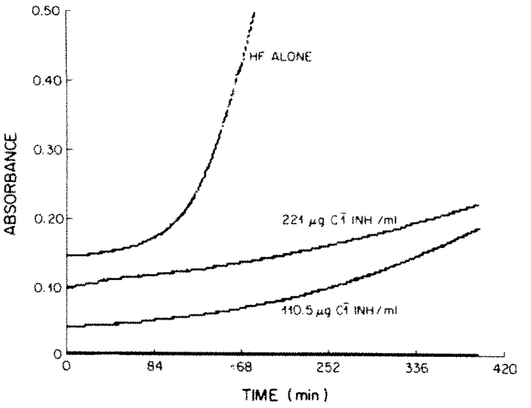

Fig 1. The effect of $\overline{\text{C1}}$ INH on HF autoactivation in glass cuvettes. HF was preincubated with phenylalanine-phenylalanine-arginine-CMK to inactivate HFa and was incubated in the absence or presence of $\overline{\text{C1}}$ INH in glass cuvettes containing S2222 (0.5 mmol/L). The HF final concentration was 4.3 ug/mL (54 nmol/L). The $\overline{\text{C1}}$ INH final concentrations were 221 ug/mL (2.1 umol/L) or 110.5 ug/mL (1.05 umol/L). The absorbance at 405 nmol/L was recorded on a Gilford Model 250 spectrophotometer interfaced with an Apple IIe computer. Initial absorbances are displaced on the Y axis by arbitrary amounts for clarity in presentation.

time points the amidolytic activity of 5 µL samples was determined. HF was not treated with phe-phe-arg-CMK in these experiments.

The data presented as the mean ± 1 SEM. The effects of temperature and $\overline{\text{C1}}$ INH concentration were analyzed by two-way analysis of variance.

SDS polyacrylamide gel analysis of HF cleavage. HF (final concentration 1 µmol/L) was incubated in the absence or presence of $\overline{\text{C1}}$ INH (final concentration 2.2 µmol/L) in polypropylene tubes for 48 hours at 37 °C. In some experiments $\overline{\text{C1}}$ INH (2.2 µmol/L) was added to HF after 48 hours and the mixture was incubated at 37 °C for an additional 30 minutes. As a control $\overline{\text{C1}}$ INH was always incubated alone for 48 hours. At the end of the incubation period, HF amidolytic activity was tested using S2222. Additional aliquots were heated in 0.125 mol/L Tris-HCl (pH 6.8), 12.5% SDS, and 25% glycerol for two minutes at 100 °C under nonreducing conditions and subsequently electrophoresed on polyacrylamide slab gels using the method of Laemmli.[17] The acrylamide concentration was 4% in the stacking gel and 10% in the separating gel. Following overnight fixation, gels were stained with Coomassie brilliant blue (R250).

RESULTS

Previous studies have demonstrated that HF autoactivates in glass tubes requiring incubation for up to two hours,[5] but in polypropylene tubes no such activity is seen during the same time period. However, when HF (1 µmol/L) was incubated at 37 °C in polypropylene tubes for up to 48 hours, a very slow autoactivation was seen, as shown in Fig 1. Little change in enzymatic activity was observed during the first eight hours of incubation and at 48 hours the amidolytic activity measured was only 4-fold greater than that present initially. Under these experimental conditions addition of various concentrations of $\overline{\text{C1}}$ INH (0.54, 1.05, and 2.10 µmol/L) demonstrated comparable inhibitory capacities; ie, even the lowest dose completely prevented the appearance of amidolytic activity and also inhibited the trace of activity seen in the starting material at time zero (Fig 2). Since bacterial growth and resultant endotoxin accumulation can lead to Hageman factor activation, particularly under conditions of prolonged incubation, this experiment was repeated in the presence of both 0.02 mol/L EDTA and 0.02% sodium azide. There was no diminution in the rate of Hageman factor activation in the presence of either bacteriostatic agent.

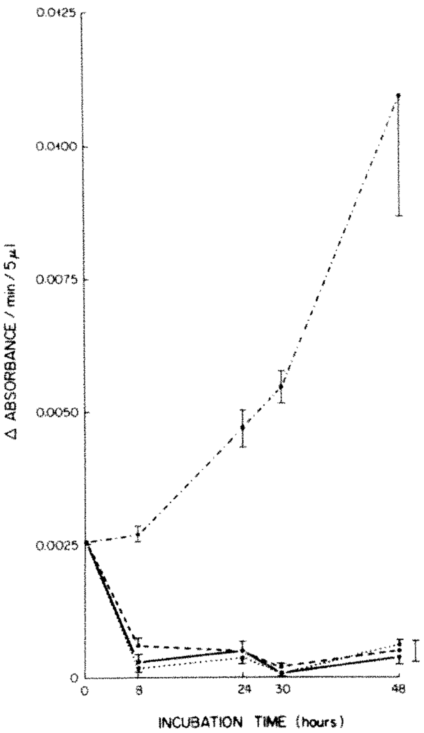

Fig 2. $\overline{\text{C1}}$ INH inhibition of HF autoactivation in polypropylene tubes. HF (1 umol/L) final concentration was incubated in polypropylene tubes with or without $\overline{\text{C1}}$ INH at 37 °C. Amidolytic activity was assayed initially and at 8, 24, 30, and 48 hours. $\overline{\text{C1}}$ INH final concentrations were 2.14 (———), 1.02 (--------), 0.54 umol/L (· · · · · ·), 0 (—.—.—). The data shown are the means ± 1 SEM from 4 separate experiments.

Exposure of native HF to a negatively charged surface by incubation in a glass cuvette accelerates autoactivation.[5] Figure 2 shows a representative experiment using 54 nmol/L HF; in order to observe the process, endogenous HFa was first inactivated by preincubation with 5 µmol/L phe-phe-arg-CMK and then introduced into cuvettes containing substrate (S2222) and different concentrations of $\overline{\text{C1}}$-INH. In the absence of $\overline{\text{C1}}$ INH, autoactivation is evident by two hours shown by the accelerating increase in absorbance. In contrast, when $\overline{\text{C1}}$ INH (1.05 and 2.10 µmol/L) was present, comparable amidolytic activity was not observed within seven hours; the degree of inhibition seen was dependent upon the concentration of C1 INH. For ease of visualization, the three curves are arbitrarily placed along the Y axis; it is the rate of change in absorbance that reflects increasing enzyme concentration. The apparent rate constant of the autoactivation can be quantitated by the slopes of semilogarithmic plots of ΔA/min v time. When examined over the time interval from 90 to 385 minutes, the slope of the secondary plot obtained with 1.05 µmol/L $\overline{\mathrm{Cl}}$ INH was 0.0067 min^{-1}, whereas that obtained with 2.10 µmol/L $\overline{\mathrm{Cl}}$ INH was only 0.0035 min^{-1}.

The temperature dependence of the effect of $\overline{\mathrm{Cl}}$ INH upon surface-induced autoactivation was then examined. In this case, DS provided an alternative source of a negatively charged initiating surface. Incubation of HF (1 µmol/L) with DS (5 µg/mL) in polypropylene tubes resulted in an increase in amidolytic activity which reached a plateau by 60 minutes when examined at ambient (25 °C), physiologic (37 °C), or lowered (4 °C) temperatures.

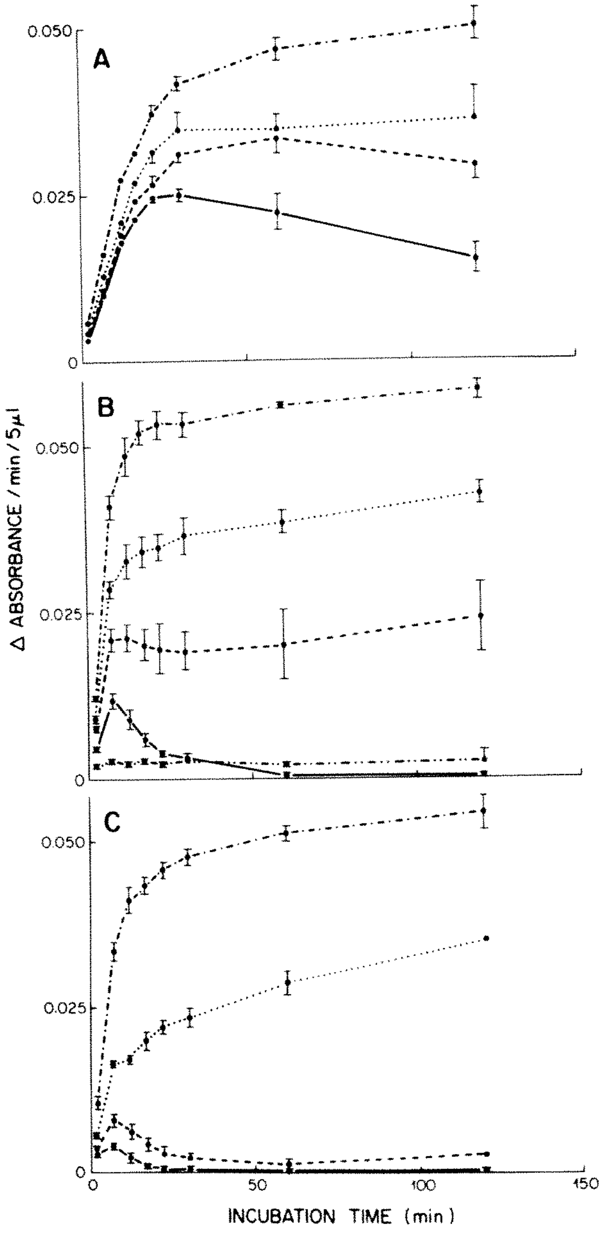

Fig 3. Effects of temperature on the Kinetics of $\overline{\mathrm{Cl}}$ INH inhibition of HF autoactivation with dextran sulfate. HF (final concentration 1 umol/L) was incubated with DS (final concentration 5 ug/mL) in the absence (—.—.—) or presence of various concentrations of $\overline{\mathrm{Cl}}$ INH: 2.1 µmol/L (———), 1.07 µmol/L (--------), or 0.54 umol/L (······). Incubation was for a period of up to two hours at each of three temperatures: (A) 4 °C; (B) 25 °C, and (C) 37 °C. In panel B, an incubation of HF without DS is shown for comparison (—··—··). In these experiments there were between 2 and 6 data points each time.

At 4 °C (Fig 3A) increasing concentrations of $\overline{\mathrm{Cl}}$ INH decreased the peak of enzymatic activity obtained at 30 to 40 minutes. At the highest concentration of $\overline{\mathrm{Cl}}$ INH used, the measured activity declined such that by 24 hours, none remained (data not shown). At 25 °C, (Fig 3B), the same general effect was seen but inhibition by $\overline{\mathrm{Cl}}$ INH was more pronounced and a clear dose response was seen. At the highest concentration, only a transient increase in activity was obtained which then promptly declined. Lesser concentrations of inhibitor appeared to decrease the magnitude of the peak of activity compared to that obtained in the absence of inhibitor. At 37 °C (Fig 3C), the two highest concentrations of $\overline{\mathrm{Cl}}$ INH markedly inhibited autoactivation, while the lowest concentration caused significant inhibition.

Comparison of Figs 3A, B, and C shows that a temperature change from 4 °C to 37 °C had little effect upon autoactivation in the absence of $\overline{\mathrm{Cl}}$ INH. The peak activity reached was similar at each temperature but was delayed somewhat at 4 °C. The data thus indicate that as the temperature is decreased from 37 °C to 4 °C, the rate of inhibition of activated HF by $\overline{\mathrm{Cl}}$ INH decreases, as has been reported previously when activated HF was tested directly.[14] The rate of autoactivation is also lower at 4 °C although it appears slightly greater at 22 °C than at 37 °C. Overall, the decline in the rate of inhibition is greater than that of autoactivation. Thus, the net result of these effects is that as the temperature decreases, the autoactivation reaction partially escapes inhibition by $\overline{\mathrm{Cl}}$ INH and greater transient concentrations of activated enzyme are reached.

In the above experiments we do not attempt to distinguish an effect upon autoactivation from inhibition of activated material in the preparation. The results shown in Figs 1, 2, and 3 could be explained by an interaction of $\overline{\mathrm{Cl}}$ INH with native HF that somehow inhibits digestion. On the other hand, $\overline{\mathrm{Cl}}$ INH might not interact with the substrate for autoactivation, but only with the activated product, (HFa), which is responsible for that digestion. In order to distinguish these possibilities, we examined the products of these reactions by SDS gel electrophoresis under nonreducing conditions. To decrease the rate of reaction, the experiment was performed in polypropylene tubes for a 48-hour time period. The $\overline{\mathrm{Cl}}$ INH was either added at zero time to assess its effect upon autoactivation or it was added after 48 hours of incubation to complex with the activated HF generated by autoactivation. The data are shown in Fig 4. Lane B is the starting HF preparation; lane C contains HF plus $\overline{\mathrm{Cl}}$ INH at time zero; and lane D shows $\overline{\mathrm{Cl}}$ INH alone (mol wt 105,000). In lane E, HF has been incubated alone for 48 hours at 37 °C and complete autodigestion has occurred with significant HFf formation since the gels are run without reduction. In lane F, $\overline{\mathrm{Cl}}$ INH has been incubated with the product of lane E for 30 minutes and complex formation is evident with formation of a doublet at an apparent molecular weight of 131,000 to 133,000. A band just beneath $\overline{\mathrm{Cl}}$ INH is seen that may represent a minor $\overline{\mathrm{Cl}}$ INH form described in plasma[18]

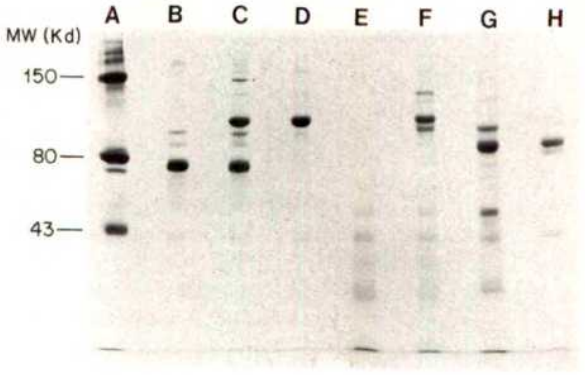

Fig 4. SDS-PAGE of HF autoactivation in polypropylene tubes in the absence or presence of $\overline{\text{C1}}$ INH. HF (final concentration 1 μmol/L), with or without $\overline{\text{C1}}$ INH (final concentration 2.2 μmol/L), was incubated in polypropylene tubes for 48 hours at 37 °C. In some cases, $\overline{\text{C1}}$ INH was added to HF at 48 hours and the mixture was incubated for 20 minutes. In addition, $\overline{\text{C1}}$ INH was incubated by itself for 48 hours. The gel was run under nonreducing conditions. The amount of each protein loaded onto the gel is as follows: MW markers (human IgG, transferrin, and ovalbumin), 2.2 μg each; HF, 2.3 μg; and $\overline{\text{C1}}$ INH, 6.3 μg. Lanes A–H: MW markers (A); HF, time 0 (B); HF and $\overline{\text{C1}}$ INH, time 0 (C); $\overline{\text{C1}}$ INH, time 0 (D); HF, 48 hours (E); HF, 48 hours and $\overline{\text{C1}}$ INH, 30 minutes (F); HF and $\overline{\text{C1}}$ INH, 48 hours (G); and $\overline{\text{C1}}$ INH, 48 hours (H).

and present in our preparation or possibly $\overline{\text{C1}}$ INH cleaved by the HFf.[19] In lane H, containing $\overline{\text{C1}}$ INH alone, two bands are more clearly seen, however after 48 hours incubation a decrease in size of about 16,000 is seen. In lane G, $\overline{\text{C1}}$ INH was incubated with HF for a 48-hour time period. HF autodigestion was not prevented since the band at apparent molecular weight of 78,000 is not seen. The trace residual HF noted compared to lane E or F suggests that autodigestion was slower with $\overline{\text{C1}}$ INH present. A complex is again observed, but it is at 98,000 rather than 133,000, presumably due to the altered mobility of $\overline{\text{C1}}$ INH (lane H). A faint band is also visible at an apparent molecular weight of 122,000.

DISCUSSION

It is clear that $\overline{\text{C1}}$ INH is capable of markedly dampening the autoactivation of Hageman factor that is initiated by interaction with surfaces (Figs 2, 3), as well as the very slow autoactivation that occurs in the fluid phase (Fig 1). The latter reaction may occur in circulating blood, assuming the absence of contact with any "activating" surface. However, when cleavage of Hageman Factor is examined after 48 hours at 37 °C in the absence of a surface, it is clear that cleavage occurs even in the presence of $\overline{\text{C1}}$ INH (Fig 4), ie, the 78,000 molecular weight band is gone. Although the activated Hageman factor that forms is subsequently inactivated (activity is zero at 48 hours), the rate and magnitude of inactivation are not sufficient to prevent digestion of the residual native Hageman factor. Furthermore, the presence of activated forms of Hageman factor suggests that no major interaction with native Hageman factor occurs. Since $\overline{\text{C1}}$ INH prevents C1 cleavage and autoactivation by interaction with the zymogen[11] in addition to its ability to bind the activated enzymes $\overline{\text{C1r}}$ and $\overline{\text{C1s}}$,[12] there is precedent for such a dual interaction. The autoactivation of C1 is intramolecular involving two C1r subunits, and the C1r subcomponent appears to have enzymatic activity in the absence of cleavage. It may be this site with which $\overline{\text{C1}}$ INH interacts. Similar experiments have failed to define an active site in native Hageman factor.[20,21]

If Hageman factor has the potential to be slowly activated in circulating blood, the activated enzyme would likely be bound to $\overline{\text{C1}}$ INH and cleared with synthesis of Hageman factor sufficient to maintain a normal level. Nevertheless, trace quantities of uninhibited enzyme may persist and we have estimated this to be no greater than one molecule in 4,000.[21] This minute level may be sufficient to initiate contact activation when a proper surface is added. Our observations on temperature dependence (Fig 3) in which the effect on autoactivation inhibition is greater than the effect on activation rate may explain in part "cold-dependent" HF activation seen with prolonged plasma incubation at varying temperatures. Further, in a disease such as hereditary angioedema, in which $\overline{\text{C1}}$ INH levels are either low[22] or the molecule dysfunctional,[23] there may be augmented Hageman factor autoactivation. If the active form accumulates, this may predispose to kinin formation[24,25] and attacks of swelling. Studies to test this hypothesis are in progress.

Ultrastructural Localization of Coagulation Factor V in Human Platelets

By June D. Wencel-Drake, Bjorn Dahlback, James G. White, and Mark H. Ginsberg

The distribution and transport in platelets of human coagulation Factor V was investigated by immunofluorescent and immunoelectron microscopy. In resting intact platelets, little surface staining was observed by immunofluorescence. In permeable resting cells, punctate staining similar to that reported for fibrinogen (Fbg), thrombospondin (TSP), fibronectin (Fn), von Willebrand factor (VWF), B-thromboglobulin (BTG), and platelet Factor 4 (PF4) was observed.[1,2] Double label immunofluorescent staining for Fbg and Factor V demonstrated colocalization, suggesting their presence in the same intracellular structure. Thrombin stimulation induced the appearance of larger (~0.5 μ) immunofluorescent masses of these proteins which exactly colocalized. Thus, at the light level, Factor V and Fbg are localized in the same structure in resting and thrombin-stimulated cells. On the ultrastructural level, an alpha granule localization for Fbg has previously been established.[3-6] We have extended our immunofluorescent observations regarding the localization of Factor V in human platelets by use of transmission electron microscopy of antibody-stained ultrathin frozen sections. In resting cells, staining of virtually all alpha granules was observed for Factor V. In contrast, consistent staining was absent from other organelles including plasma membranes, mitochondria, and vacuolar structures which may represent the open canalicular system. These data thus establish at the ultrastructural level an alpha granule localization of human coagulation Factor V.

BLOOD coagulation Factor V is a relatively inactive procofactor with Mr = 330,000.[7] Catalytic amounts of thrombin results in limited proteolysis of the single chain Factor V which correlates with a 10- to 80-fold increase in activity.[7] Factor Va functions as an essential nonenzymatic cofactor of the prothrombinase complex by combining with Factor Xa, Ca^{2+}, and the platelet surface (or an alternative phospholipid surface) to catalyze the conversion of prothrombin to thrombin.[8] It has long been recognized that Factor V activity is associated with platelets[9,10] and can be expressed following repeated freeze-thawing of platelets,[9] suggesting an intracellular localization of Factor V. Recently, Chesney et al[11] have demonstrated that release of Factor V induced by collagen is inhibited by antimycin A or 2-deoxyglucose, suggesting that Factor V release is a secretory process. Several lines of evidence have suggested that Factor V is associated with platelet alpha granules: (1) Subcellular fractionation studies indicate that Factor V coisolates with an alpha granule–rich fraction as measured by a functional one-stage assay for Factor V activity[11]; (2) The kinetics of release of Factor V parallels that of platelet factor 4, a known alpha granule protein.[1-6,12-14] In contrast, Gray platelets are selectively deficient in alpha granules,[15,16] yet they have been reported to contain near-normal amounts of Factor V antigen,[17] thereby arguing against an alpha granule localization. The aim of the present study was to establish the subcellular localization of Factor V in the resting cell by use of immunolocalization techniques. In addition, since surface expression of Factor V is required for its procoagulant function, we wished to determine whether the mechanism by which Factor V reaches the cell surface parallels that which has been suggested for alpha granule proteins.[1,2]

MATERIALS AND METHODS

Chemicals. The following were purchased from Sigma Chemicals (St. Louis, Mo): poly-L-lysine, bovine serum albumin, and cacodylic acid. Paraformaldehyde and EM grade glutaraldehyde were obtained from Polysciences (Warrington, Pa). Sepharose 2B and dextran T-10 were obtained from Pharmacia (Piscataway, NJ). Triton X-100 was purchased from J.T. Baker Chemicals (Phillipsburg, NJ). Phosphotungstic acid was purchased from Ted Pella, Inc. (Tustin, Calif).

Platelet preparation. Platelet-rich plasma was prepared from acid citrate dextrose anticoagulated whole blood obtained from healthy aspirin-free volunteers as described.[18] Washed human platelets were subsequently prepared by centrifugation and gel-filtration on Sepharose 2B as described.[19]

Purified proteins. Purified human alpha-thrombin was the generous gift of Dr John Fenton, New York State Department of Health, Albany, NY. This material was diluted to 100 u/mL in modified Tyrode's buffer, stored in aliquots at −70 °C, and thawed once prior to use. Purified human fibrinogen was prepared as previously described.[20] Human coagulation Factor V was prepared according to the method of Dahlback[7] with the following modification: the molarity of the NH_4Cl in the buffer used to dissolve the polyethylene glycol precipitate was lowered to 0.05 mol/L from 0.1 mol/L, to ensure binding to the DEAE-sepharose. The purified material produced a single Coomassie blue staining band of apparent Mr = 330,000, under reducing conditions in 5% to 10% SDS-polyacrylamide gels. Purified Factor V (0.5 mg/mL in 50% glycerol, 25 mmol/L Tris-HCl, pH 7.5, 0.05 mol/L NH_4Cl, 5 mmol/L benzamidine, and 5 mmol/L $CaCl_2$) was labelled with ^{125}I by the lactoperoxidase method of Thorell et al.[21] The labelled Factor V was isolated by gel filtration on a 0.9 × 55 cm column packed with

Ultrogel AcA 34 in 50 mmol/L Tris-HCl, pH 7.5, 0.1 mol/L NH_4Cl, 0.10 mmol/L benzamidine, 1.0 mmol/L DFP, 10 mmol/L $CaCl_2$ containing 5 mg/mL bovine serum albumin. The labelled Factor V was stored at −20 °C after the addition of an equal volume of glycerol.

Antibodies. Rabbit antihuman Fbg was prepared and characterized as previously described.[2] Rabbit antihuman Factor V, for use in immunofluorescent, immunoelectronmicroscopy, and Western blotting studies, was prepared by immunization of rabbits with our purified single chain Factor V preparation by Dakopatts Inc (Glostrup, Denmark). The antiserum, a concentrated IgG fraction, was immunoadsorbed until a single precipitin line was obtained when tested against plasma in crossed immunoelectrophoresis. Additionally, a single line of identity among plasma Factor V, purified Factor V, and platelet extract was observed in the ouchterlony system. Following adsorption of the antibody with purified Factor V, no immunoprecipitable material was observed when tested against plasma, purified Factor V, or a platelet extract. Rabbit antisera specific for Factor V fragments D and F_1F_2, for use in Western blotting studies, were prepared as previously described.[22]

Western blotting. For Western blotting studies, platelets were prepared as previously described[22] and kept at room temperature in the washing buffer at a cell concentration of 9×10^8 cells/mL. 200 uL aliquots were drawn and pelleted in Eppendorf tubes by centrifugation at 15,600 x g at room temperature for two minutes. The pelleted platelets were dissolved in hot sample preparation buffer containing 3% SDS and 2% B-mercaptoethanol. Identical patterns were obtained when the pellet was first dissolved in a Tris or phosphate-buffer containing 2% Triton X-100, 5 mmol/L diisopropylphosphofluoridate, 1 mmol/L phenylmethylsulfonyl flouride, 10 mmol/L benzamidin, 10 mmol/L EDTA, and 50 ug/mL Leupeptin, and then mixed with the boiling sample preparation buffer.

In previous studies, analysis of purified Factor V revealed a single bank of apparent Mr = 330,000.[7] However, Western blotting analysis of whole platelet extracts revealed several lower molecular weight bands including a doublet at Mr = 220,000 and a band at Mr = 150,000, in addition to the Mr = 330,000 band (Fig 1, lane 1). Subsequent Western blotting analyses of whole platelet extracts using well-characterized anti-Factor V fragment D, or anti-Factor V fragment F_1F_2–specific antibodies[22] demonstrates that the doublet at 200 kd reacts with the F_1F_2 antiserum, indicating that it is the C-terminal half of Factor V, whereas the 150 kd band, reacting with the anti-D antiserum, is the N-terminal half of Factor V (Fig 1, lanes 2 and 3). To test whether Factor V was present in platelets in this form or degraded as a result of platelet lysis, platelet extracts were spiked with ^{125}I-labeled Factor V and run on SDS gels. Western blot analysis of this material revealed bands at Mr = 330,000, 220,000, and 150,000 (Fig 1, lane 4) that exactly corresponded to bands derived from ^{125}I-Factor V on the companion autoradiogram (Fig 1, lane 5). Figure 1, lane 6 confirms that ^{125}I-Factor V existed as the single chain form with an Mr = 330,000, prior to addition to the platelet extract. These data suggest that platelet Factor V may be single chain but becomes proteolysed during the extraction of platelets for electrophoresis, presumably due to platelet-derived proteases, a process that is not fully inhibited by hot sample preparation buffer nor by the inhibitor mixture discussed above.

Immunofluorescence. Immunofluorescent staining of platelets was performed as described.[2] Briefly, resting or thrombin-treated platelets were fixed with 2% paraformaldehyde on ice for one hour. Unreacted aldehyde was blocked with NH_4Cl–Tris buffered saline, pH 7.4, and the cells were permitted to settle on polylysine-coated glass coverslips. In some cases, the cells were treated with 0.1% Triton X-100 for three minutes to render them permeable to antibody prior to staining. The permeable or intact cells were then incubated for 20 minutes with either specific antibody or preimmune rabbit serum. The cells were rinsed with Tris buffered saline containing 0.1% bovine serum albumin, and stained for 20 minutes with fluorescein-labeled goat $F(ab')_2$ antirabbit IgG (Cappel Laboratories, Cochranville, Pa). The cells were counterstained for 20 minutes with a rhodamine conjugated goat $F(ab')_2$ antihuman fibrinogen. The platelets were viewed with a Zeiss Universal microscope equipped with an HBO 50W mercury lamp and IVFI epifluorescence condenser with a BP 546 excitation filter, a KT 580 chromatic splitter, and an LP 590 barrier filter, and were photographed using Tri-X Panchromatic film.

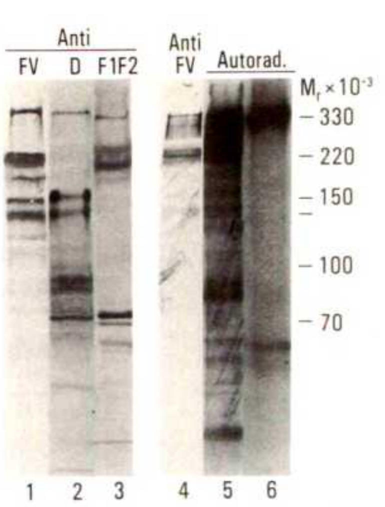

Fig 1. Western blot analysis of rabbit antihuman Factor V antibody. Lanes 1–4 are Western blot analyses, of 5% to 15% SDS-polyacrylamide gels run under reducing conditions, using either rabbit antihuman Factor V (lanes 1 and 4), rabbit antihuman Factor V fragment D specific (lane 2), or rabbit antihuman Factor V fragment F_1F_2–specific (lane 3) antibodies. Peroxidase-labelled goat antirabbit IgG was employed as the secondary antibody. Lanes 1–4 are blots of pelleted washed platelets (~5×10^7/lane) that were dissolved in boiling sample preparation buffer as described in Materials and Methods. Lanes 4 and 5 show the Western blot and companion autoradiograph of a platelet extract that had been spiked with an ^{125}I-labelled tracer of single chain human Factor V prior to boiling with sample preparation buffer. The autoradiography of the tracer mixed with cold human Factor V is seen in lane 6. The relative molecular weights of the components are indicated at the right.

Fixation and cryoultramicrotomy. Fixed platelets for sectioning were prepared by adding a mixture of 2% paraformaldehyde and 0.1% glutaraldehyde at 37 °C to a suspension of washed cells in 0.1 mol/L $NaPO_4$, pH 7.4, at 37 °C. The cells were then mixed and placed on ice for 15 minutes at 4 °C. Unreacted aldehyde was blocked by treatment with NH_4Cl–Tris buffered saline at pH 7.4 and the cells were subsequently embedded in a low gelling temperature agarose. Agarose blocks were infused with 0.8 mol/L sucrose as cryoprotectant for 30 minutes, mounted on copper bullets, and stored in liquid nitrogen until sectioning.

Sectioning was performed at −84 °C according to the method of Tokuyasu and Singer,[23,24] utilizing a Sorvall MT 2-B ultramicrotome with an LTC-2 cryokit attachment (DuPont Instruments, Sorvall Biomedical Division, Newton, Conn). Sections ranging in thickness between 800 and 1000 angstroms were transferred to a parlodion and carbon-coated copper grid by means of a thin wire loop containing a drop of 2.3 mol/L sucrose, which thawed en route to the grid. Half micron frozen thick sections, for immunofluorescence, were obtained by sectioning at −54 °C. Sections were transferred to acid washed glass slides and stained as described for whole cells.

Immunolabelling and negative staining. Rabbit antihuman Factor V or preimmune rabbit serum were used as primary antibodies in an indirect immunolabelling procedure. Affinity purified and biotinylated goat antirabbit IgG (Hyclone Laboratories, Logan Ut) was used as the second antibody. Antibody-antigen interactions were visualized by means of a colloidal gold-avidin conjugate.

Five nanometer colloidal gold-avidin was prepared as previously described.[6] Prior to immunolabelling, the thawed ultrathin frozen sections were conditioned with 2% gelatin and 0.1% bovine serum albumin. Following completion of immunolabelling, the sections were negatively stained with a mixture of 0.2% phosphotungstic acid and 1% dextran. Sections were viewed on a Hitachi 12-A transmission electron microscope with an accelerating voltage of 75 KV, and were photographed with Kodak electron microscope film No. 4489.

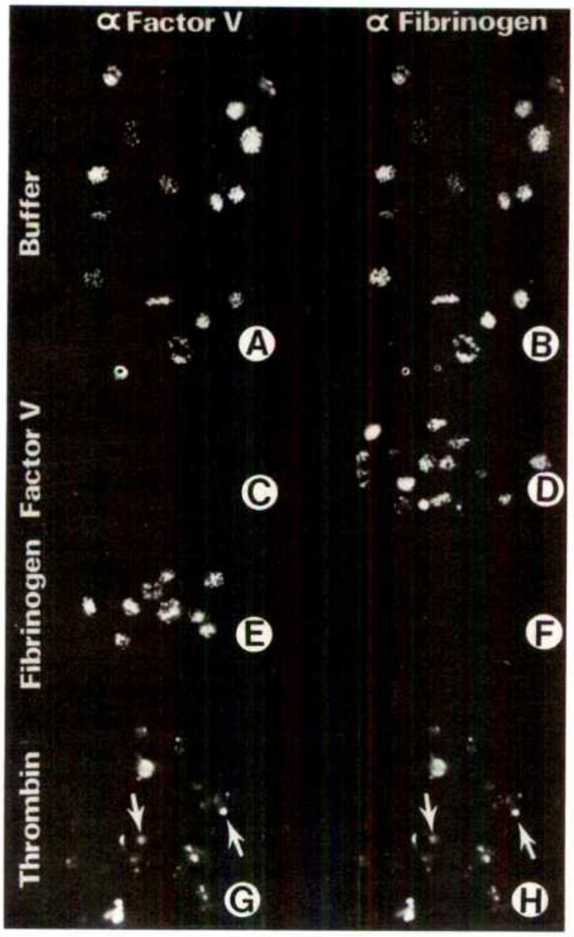

Fig 2. Colocalization of Factor V and Fbg in resting and thrombin-stimulated platelets. Resting, permeable platelets were stained with a mixture of rabbit antihuman Factor V and rhodaminated goat F(ab′)$_2$ antihuman Fbg and counterstained with fluoresceinated goat F(ab′)$_2$ antirabbit IgG. Antibodies absorbed with buffer alone (A and B) demonstrated punctate intracellular staining for Factor V which exactly colocalized with Fbg. Incubation of the antibody mixture prior to staining with either purified Factor V (C and D) or Fbg (E and F) only blocked fluorescence when an antibody was absorbed with its parent antigen. When platelets were fixed one minute following thrombin stimulation, we noted the appearance of large, peripheral immunofluorescent masses which are defined as smooth fluorescent structures ≥ 0.5 μm in diameter and which double stained for Factor V and Fbg (G and H, arrowheads); Original magnification, ×1,400; Current magnification, ×1,050.

RESULTS

Localization of Factor V in resting and thrombin-stimulated platelets. Intact resting platelets demonstrated minimal surface staining. When cells were made permeable with Triton X-100, however, punctate immunofluorescent staining for Factor V and Fbg was observed. Antibody specificity was documented in double-label immunofluorescent cross-blocking studies. In these studies, mixtures of rabbit antihuman Factor V antibody and rhodaminated goat F(ab′)$_2$ antihuman Fbg were absorbed overnight at 4 °C with either a 1.4-fold molar excess of purified Fbg, or an equimolar concentration of purified Factor V or buffer. Permeable platelets were subsequently stained with these absorbed antibodies and counterstained with fluoresceinated goat F(ab′)$_2$ antirabbit IgG. As shown in Fig 2A and B, antibodies absorbed with buffer alone demonstrated punctate intracellular staining for Factor V which exactly colocalizes with Fbg. However, when platelets were stained using the absorbed antibodies, fluorescence was blocked only when an antibody was absorbed with its parent antigen, confirming specificity of staining (Fig 2C and F). Additionally, control testing with preimmune rabbit or goat IgG failed to stain either intact or permeable cells (data not shown).

To determine the localization of Factor V antigen immediately following thrombin stimulation, cells fixed after one minute's stimulation at 24 °C were double stained for Factor V and Fbg. Thrombin stimulation resulted in the time-dependent translocation of Fbg and Factor V into larger immunofluorescent masses similar to those that have been reported for TSP, Fn, VWF, BTG, and PF4 (Fig 2G and H).[1,2] These masses were defined as smooth fluorescent structures, ≥ 0.5 microns in diameter, and were not seen in

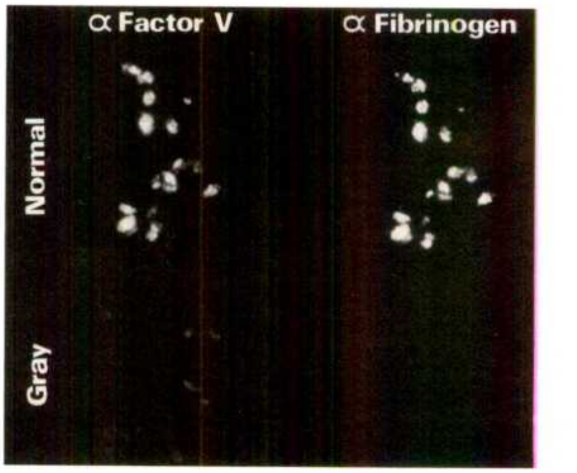

Fig 3. Reduced immunofluorescent staining for Factor V and Fbg in Gray platelets. Frozen thick sections of normal and Gray platelets were double stained for Factor V and Fbg as described in Materials and Methods. The left panels illustrate Factor V staining and the right illustrate Fbg staining of the same field of platelets. Normal cells are depicted in the upper panels and gray platelets are shown below. Original magnification, ×1,400; Current magnification, ×770.

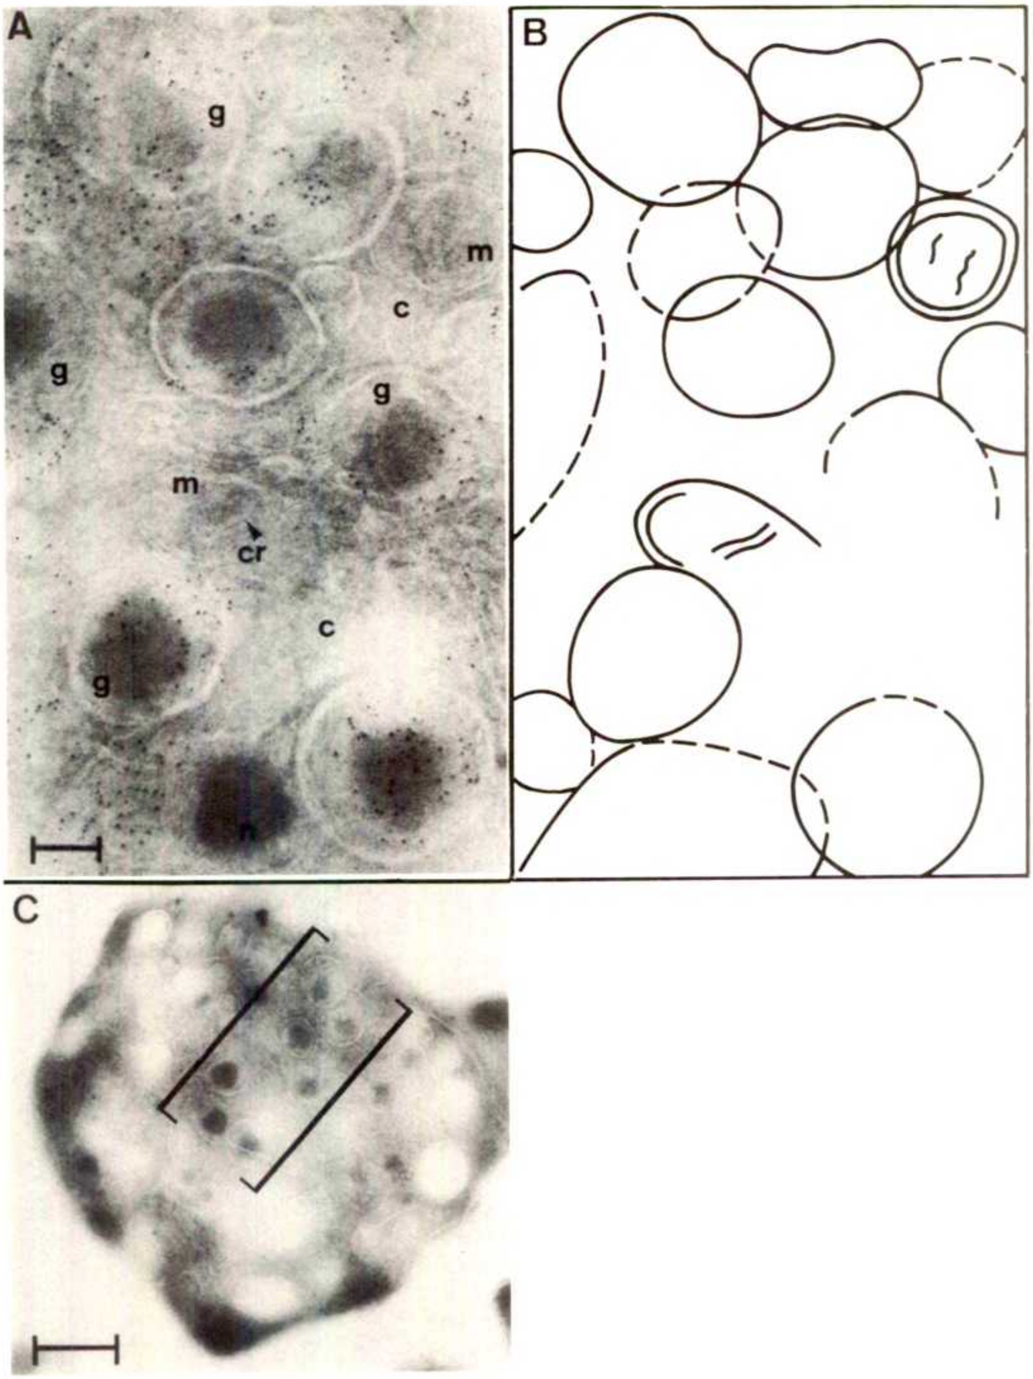

Fig 4. Indirect immunolabeling of Factor V in cryostat sections of human platelets. Ultrathin frozen sections were incubated with rabbit antihuman Factor V as the primary antibody. Biotinylated goat antirabbit IgG was employed as the second antibody. Antibody-antigen interactions were visualized by means of a 5 nm colloidal gold-avidin conjugate. Panel A, a magnification of the whole cell shown in panel C, demonstrates heavy labeling over structures identified as alpha granules (g) with minimal labeling of mitochondria (m), cristae (cr), or the platelet cytosolic matrix (c). Panel B represents a corresponding illustration, with intact membranes designated by solid lines and presumptive membranes, by dashed lines, (original magnification (A), 107,500 X, bar 0.1 μm; current magnification, 80,625 X; (B) original magnification, 107,500 X; current magnification, 80,625 X; (C) original magnificationm 28,000 X, bar 0.5 μm; current magnification, 21,000 X).

resting cells. The above data suggested that Factor V and Fbg are stored in the same intracellular organelle and are processed to the cell surface via common structural intermediates.

As an alpha granule localization for Fbg has been established,[3-6] it seemed likely that platelet Factor V would also be stored in alpha granules. To examine this possibility frozen thick sections of gray platelets, which are selectively deficient in alpha granules,[15,16] were double stained for Factor V and Fbg. As seen in Fig 3, immunofluorescent labeling of gray platelets revealed markedly decreased staining for both Factor V and Fbg (lower panels) when compared to normal platelets (upper panels).

Ultrastructural localization of Factor V in frozen thin sections. To investigate the ultrastructural localization of Factor V by transmission electron microscopy, we prepared negatively stained, ultrathin frozen sections of resting platelets. Platelet morphology in negatively stained cryosections has been described previously.[6] Alpha granules are identified on the basis of their size, 0.1 to 0.4 u, roughly spherical shape, single limiting electron lucent membrane of 100 ± 21 angstroms in thickness, and the occasional appearance of a darkly staining eccentric nucleoid. Other identifiable subcellular organelles include mitochondria with characteristic double membranes and cristae.

Indirect immunolabelling of frozen sections with an anti-Factor V antibody demonstrated heavy labelling of structures identified by the above criteria as alpha granules (Fig 4A). The labelling pattern was neither restricted to the nucleoid nor to the electron lucent periphery, but rather appeared inhomogenous. In contrast, label was absent from plasma membrane and mitochondria. Only background levels of staining were associated with the platelet cytoplasmic matrix. In contrast, control sections, stained with preimmune rabbit serum, demonstrated only occasional random colloidal gold particles (not shown).

DISCUSSION

In the present study we have investigated the intracellular localization of human coagulation Factor V and its initial redistribution in response to thrombin. Utilizing immunofluorescence techniques we have found that Factor V and Fbg colocalize in the interior of resting platelets. On the ultrastructural level, Factor V was localized within structures morphologically identified as alpha granules by means of indirect immunolabeling of ultrathin frozen sections. Following thrombin stimulation, Factor V is consolidated into larger structural intermediates which double stain for Fbg.

It has long been recognized that Factor V is an essential cofactor in the assembly of the prothrombinase complex.[8,25] Activated Factor V (Factor Va) functions as the platelet-bound receptor for activated Factor X (Factor Xa).[26] While the platelet receptor for Va does not require platelet release for its expression,[26] platelet Factor V contributes to functional prothrombinase complex assembly.[17] In this regard, subcellular fractionation studies have suggested an alpha granule localization for Factor V.[11] However, in recent studies Tracy et al[17] have suggested that normal Factor V levels are present in Gray platelets (which are selectively deficient in alpha granules).[15,16] While these results may represent partially activated platelets with surface-bound Factor V or reflect heterogeneity among gray platelet patients (as the patient we examined demonstrated markedly reduced Factor V antigen as judged by immunofluorescence), the present studies and the subcellular fractionation studies of Chesney et al[11] localize the bulk of Factor V antigen in the resting cell to alpha granules. Additionally, following thrombin stimulation, Factor V was shown to become consolidated into larger structural intermediates that double stain for Fbg and have been suggested to represent compound granules.[1] Thus, intraplatelet Factor V is apparently stored and processed to the cell surface by a mechanism common to a growing number of alpha granule proteins.[1,2] Whether the apparent functional differences between platelet and plasma Factor V[17] are due to structural differences, as has been shown for von Willebrand factor, another alpha granule protein,[27] or simply reflect a local concentration effect brought on by a fusing compound granule, remains to be evaluated.

An In Vitro Model of Erythroid Egress in Bone Marrow

By Richard E. Waugh and Mohamed Sassi

An in vitro system has been developed that mimics the passage of erythrocytes from the bone marrow to the circulation. Bone marrow egress and its proper regulation are vital physiologic processes. However, because of the inaccessibility of the marrow, it is difficult to evaluate the various factors important in controlling these processes or even to define the precise mechanism by which egress occurs. The in vitro system has been designed to evaluate the importance of different physical parameters in regulating egress. It consists of a thin silicon wafer (thickness ≃ 1.0 μm) cemented over the tip of a large (15.0 μm ID) micropipette. The wafer contains a single circular pore. Cells were observed under the microscope as they passed through the pore under controlled pressures. The rate and duration of passage were obtained from videorecordings of the experiment. The measured passage times agreed well with the predictions of a simple analytical model of a cell passing through a thin aperture. The experimental results confirm the conclusion reached from the analysis that the pressures needed to drive a cell through the pore are well within the physiologic range, and the time needed to complete egress is typically less than 1.0 seconds. These results support the hypothesis that erythrocyte egress may be driven by a hydrostatic pressure difference across the pore.

© 1986 by Grune & Stratton, Inc.

AN average adult man has approximately 2.5 × 10^{13} red blood cells in circulation at any given time, and the average lifespan of each cell is approximately 120 days. To maintain homeostasis, the bone marrow must supply about 2.5 × 10^6 new erythrocytes to the circulation every second. To get from the hemopoietic space, where the cells grow and differentiate, to the marrow sinuses, which are contiguous with the circulation, the cells must pass through small apertures in the endothelial barrier separating the two compartments. These apertures are generally less than 1.0 μm in thickness and range in diameter from 1.0 μm to 3.0 μm.[1] The mechanism by which the cells pass through these apertures and the factors that regulate the flux of cells across the endothelial boundary are not well understood. We have developed an in vitro model of the egress process to evaluate the importance of different physical parameters in controlling this process.

The motivation for these investigations came from examining electron micrographs of reticulocytes in passage through endothelial pores in the bone marrow of the mouse (Fig 1). The spherical contour of the portion of the cell in the sinus suggested to us that reticulocyte egress may be driven by a hydrostatic pressure difference across the pore. An approximate analysis was undertaken[2] to obtain estimates for the time it should take a cell to complete egress at different pressures and to evaluate the importance of pore diameter and membrane viscoelastic properties on the rate of egress. Based on this analysis, it was concluded that there is a threshold pressure on the order of 1.0 to 3.0 mmHg below which the cell would not pass through the pore because of the elastic resistance of the membrane to deformation. It was also concluded that for pressures appreciably greater than the threshold pressure, the time required for the cell to complete its passage was short, typically less than 0.5 seconds.

In the present paper an experimental system has been developed to test the analytical predictions. A thin (~1.0 μm) silicon wafer with a single pore in it was cemented with epoxy over the tip of a large (15.0 μm ID) micropipette, and single erythrocytes were observed as they passed through the pore. The time course of the passage was observed as a function of the driving pressure. The experimental results agreed well with the analytic predictions. These observations support the hypothesis that erythrocyte egress may occur through preexisting endothelial pores and be driven by hydrostatic pressure.

MATERIALS AND METHODS

Cells were obtained by finger prick and suspended in a buffered saline solution containing 125 mmol/L NaCl, 24.4 mmol/L Na_2HPO_4, 6.1 mmol/L KH_2PO_4, 1.0 μmol/L sodium azide, and 3.0 mg/mL bovine serum albumin. The cell suspension was placed on the stage of an inverted microscope (Nikon M) in a chamber (1.0 × 1.0 × 0.1 cm) that allowed access for micropipettes from opposite sides. Experiments were performed at room temperature (~25 °C). The pipette-pore was connected via continuous water connection to an enclosed reservoir. Zero pressure across the pore was set by positioning the water-filled reservoir such that particles in or near the opening remained stationary. Changes in pressure relative to zero were produced by pressurizing the enclosed reservoir with an air-filled syringe. The pressure was monitored with a differential pressure transducer. The pipette-pore was introduced into the chamber on the microscope stage and an ordinary micropipette was introduced from the other side. The second pipette was used to manipulate cells from the bottom coverglass to a place near the pore opening. The cell was sucked into the pipette-pore, then a constant outward pressure was set using the air-filled syringe. The passage of the cell out of the pore under constant pressure was observed, then the cell was reaspirated into the pore and the expulsion was repeated at a different pressure. Several passages at different pressures were observed for each cell. Experiments were recorded on videotape along with a digital display of the trans-pore pressure and the time. If the pressure varied during the course of the passage the data for that passage were disregarded. The height of the cell projection outside the pore was obtained from the recordings by frame-by-frame analysis. The total time for passage at the different pressures was also noted.

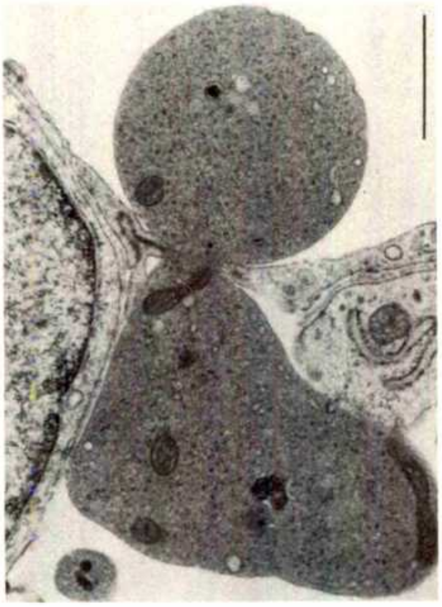

Fig 1. **This transmission electron micrograph shows the spherical projection of a reticulocyte into the blood sinus during egress in the bone marrow of a mouse (Bar = 1.0 μm). (Reprinted with permission.[1])**

The pipette-pore assembly. The assembly process is depicted diagramatically in Figs 2(A–D). The silicon wafer pore was manufactured at the National Resource and Research Facility for Submicron Structures at Cornell University. Wafers were thinned to a thickness of approximately 1.0 μm, and a pattern was etched through the wafer (Fig 2A). Pipettes were formed from microneedles pulled on a David Kopf Instruments pipette puller. The needles were ground to a flat tip against an aluminum oxide surface in an ultrasonic bath. The intensity of the bath was adjusted using a Variac transformer. After a flat tip of the desired diameter was formed, the pipette was bent at a 90° angle using a microforge (Stoelting) mounted on the stage of the microscope (see Fig 2B).

To attach the pore to the pipette, the wafer was placed on a glass slide on the microscope stage, and a ring of ultraviolet-sensitive adhesive (Crystal Clear Adhesive, Loctite Corporation, Cleveland, Ohio) was painted around the pore to match the pipette circumference. The pipette was positioned such that the opening faced toward the objective and was centered over the pore (Fig 2C). The pipette was lowered onto the wafer with a micromanipulator until it contacted the glue and formed a seal. The assembly was exposed to ultraviolet light to harden the glue. Then using the micromanipulator the pipette was pressed down onto the wafer until the pore was punched out of the wafer along the perforated ring (Fig 2D).

Prior to the experiment, the pipette-pore assembly was filled with filtered, phosphate-buffered saline. The pipette-pore was inserted into a sealed, saline-filled chamber and the chamber was pressurized by depressing the plunger of a syringe, forcing saline through the pore into the tip of the micropipette. When the tip was filled, the pipette-pore was removed from the chamber and the shaft of the pipette was filled from the back using a 31 gauge needle.

Theoretical background. An approximate analysis of an erythrocyte passing through a thin, circular aperture has appeared elsewhere,[2] and only a brief description of the analysis will be given here. The geometry used to approximate the cell contour is shown in Fig 3. The undeformed membrane consists of two flat disks of radius R_{Do}, connected at the edge. To simulate egress, the upper disk is deformed into a spherical section. The area of the surface is conserved, but the cell volume is allowed to change freely. (Volume conserving models proved to be analytically intractable.) As the

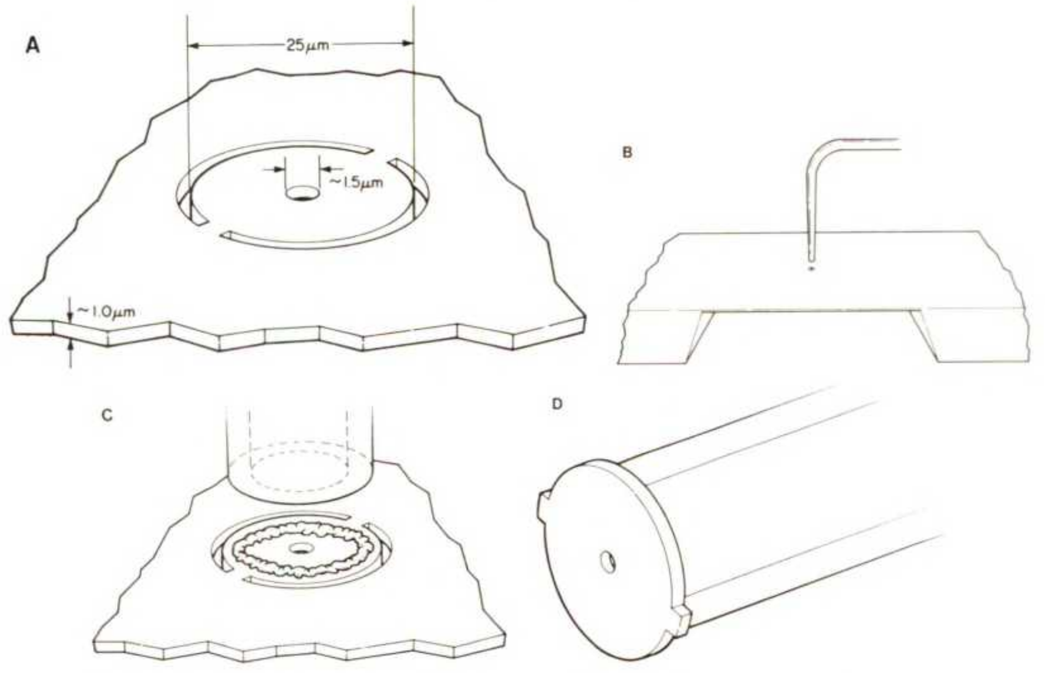

Fig 2. **This series of schematic drawings shows the procedure for assembling a pipette-pore. (A) A pattern is etched through a thin silicon wafer. The pore is at the center of a solid disk with two tabs holding the disk to the rest of the wafer. (B) A glass micropipette is bent to a 90° angle and the mouth of the pipette is centered above the pore. (C) A second pipette is used to paint a ring of adhesive onto the silicon disk where the face of the pipette will come to rest. (D) After the adhesive has cured, the disk is pressed out of the wafer and removed. The final assembly is shown.**

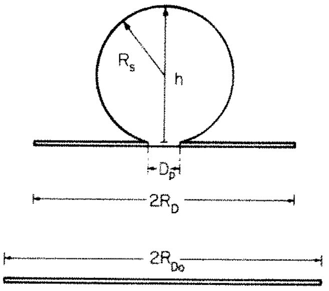

Fig 3. A schematic drawing of the geometric model used in the analysis. The initial cell radius is R_{Do}. The pore diameter is D_p. The radius of the spherical projection is R_s and its height is h. The instantaneous cell diameter, R_D, decreases with time as more material passes through the pore. (Reprinted with permission.[2])

spherical projection grows, material is drawn from the lower disk and radially across the upper disk to the pore edge (radius = R_p). When the radius of the lower disk equals R_p, egress is complete.

A simple viscoelastic constitutive equation is used to describe the membrane material behavior[3]:

$$T_s = \frac{\mu}{2}(\lambda^2 - \lambda^{-2}) + 2\eta V_s \tag{1}$$

where T_s is the maximum shear resultant at a material point, μ is the surface shear modulus, λ is the material extension in the radial direction relative to the unstressed geometry, η is the membrane surface viscosity, and V_s is the rate of material deformation. Values for μ and η were taken from the literature: $\mu = 0.007$ dyn/cm[4] and $\eta = 0.0005$ dyn s/cm.[5] The resistance of the cell to entering the pore is due to the viscoelastic deformation of the planar disk surface as it is drawn toward the aperture. In the planar region, the balance of forces in the radial direction is given by,[6]

$$\frac{dT_m}{dr} = \frac{-2T_s}{r} \tag{2}$$

where T_m is the principal membrane tension in the radial (meridional) direction and r is the radial coordinate. A differential equation is obtained by combining Equations 1 and 2 to eliminate T_s. Solution of the equation requires two boundary conditions. At the edge of the pore ($r = R_p$) we take $T_m = \Delta PR_s/2$, where R_s is the radius of the spherical section that has passed through the pore and ΔP is the pressure difference across the pore. At the edge of the cell ($r = R_D$) we take $T_m = 0$. The solution to the integration results in a first order differential equation relating the height of the spherical projection, h, to time. In terms of dimensionless quantities this takes the form:

$$\frac{d\bar{h}}{d\bar{t}} = \left\{\Delta\bar{P}\left(\bar{h} + \frac{1}{\bar{h}}\right) - \frac{\bar{h}^2}{2} - \ln\left[\left(1 - \frac{\bar{h}^2}{\bar{R}_{Do}^2}\right)(\bar{h}^2 + 1)^{1/2}\right]\right\} \cdot \left[2\bar{h} - \frac{4\bar{h}}{2\bar{R}_{Do}^2 - \bar{h}^2}\right]^{-1}, \quad A_s \le A_{1/2} \tag{3}$$

and:

$$\frac{d\bar{h}}{d\bar{t}} = \left\{\Delta\bar{P}\left(\bar{h} + \frac{1}{\bar{h}}\right) + 1 - \bar{R}_{Do}^2 - \frac{\bar{h}^2}{2} + \frac{1}{2}\ln\left[2\bar{R}_{Do}^2 - \bar{h}^2 - 1\right]\right\} \cdot \left[2\bar{h} - \frac{4\bar{h}}{2\bar{R}_{Do}^2 - \bar{h}^2}\right]^{-1} \quad A_s > A_{1/2} \tag{4}$$

where A_s is the area of the spherical section and $A_{1/2}$ is half of the total cell area.

The variables in these expressions are

$$\bar{h} = h/R_p$$
$$\Delta\bar{P} = \Delta PR_p/4\mu$$
$$\bar{R}_{Do} = R_{Do}/R_p$$
$$\bar{t} = t \cdot \mu/\eta$$

where ΔP is the pressure across the pore, R_p is the pore radius, R_{Do} is the radius of the undeformed disks, and h is the height of the spherical section (see Fig 3). Two expressions are required because of the different relationships between λ and r for material that was originally on the upper or lower disk. Before half of the cell passes the pore edge, the integral encompasses regions from both the upper and lower disks (Equation 3). After half of the cell passes the pore edge (Equation 4), only material originally from the lower disk remains in the planar region.

Equations 3 and 4 were integrated numerically using Simpson's Rule to obtain the height of the spherical projection as a function of time, as well as the total time for egress for a given set of parameters, ΔP, R_{Do}, and R_p. It is important to recognize that there is a threshold pressure, ΔP_{min}, below which egress does not occur.[2] Mathematically this occurs because for $\Delta P < \Delta P_{min}$, dh/dt becomes zero before egress is completed; hence the integration of Equations 3 and 4 cannot be completed. Physically this occurs because the pressure must be sufficient to overcome the elastic resistance of the mem-

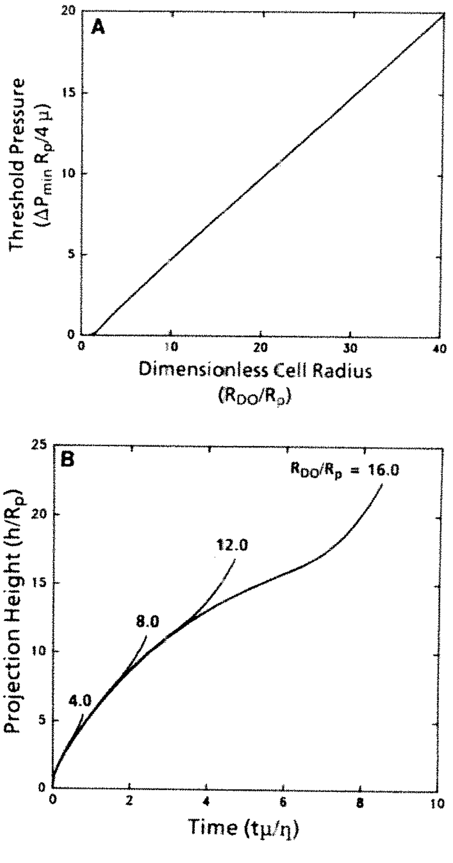

Fig 4. Results of the Analysis. (A) The dependence of the dimensionless threshold pressure ($\Delta PR_p/4\mu$) on the dimensionless cell radius (R_{Do}/R_p). Note that for a cell radius of 4.0 μm and a pore radius of 0.5 μm ($\bar{R}_{Do}$ = 8.0) the minimum pressure for egress is less than 2.0 mm Hg (2.7 × 10^3 dyn/cm^2) ($\Delta\bar{P}$ ~ 4.75). (B) The effect of changing $\bar{R}_{Do}$ on the time course of egress. $\Delta\bar{P}$ is held constant ($\Delta\bar{P}$ = 10.0). For larger values of $\bar{R}_{Do}$ the final value of $\bar{h}$ is larger because the membrane has more surface area.

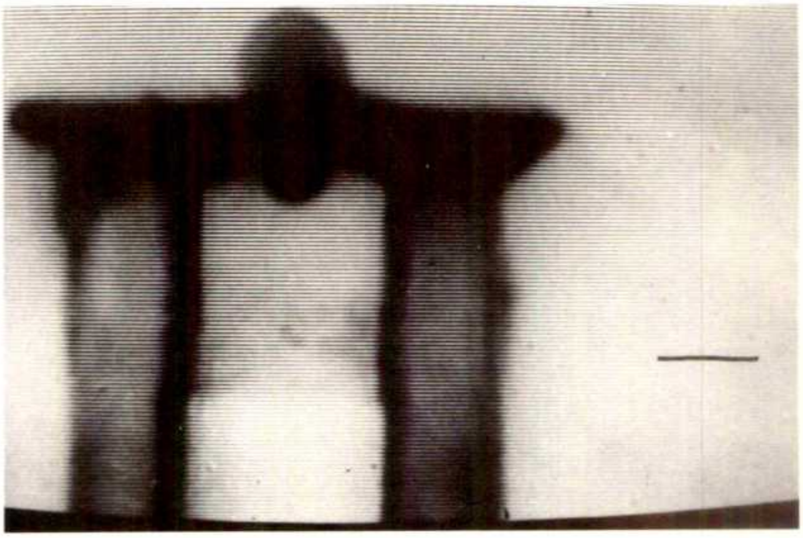

Fig 5. A photograph taken from the television monitor showing a cell passing through the pipette-pore. The driving pressure was 1.87×10^3 dyn/cm², and the total time to complete the passage was approximately 0.3 seconds (Bar = 5.0 μm).

brane. The dependence of ΔP_{min} on the dimensionless cell radius (R_{Do}/R_p) is shown in Fig 4A. When ΔP_{min} is exceeded, the cell passes through the pore. The time course of the passage also depends on the dimensionless cell radius, as is shown in Fig 4B.

Several assumptions are implicit in the analysis. The viscous resistance of the cytoplasm and the bending stiffness of the membrane are neglected. The interaction between the membrane and the pore is assumed to be frictionless. The surface geometry is constrained, no folding or wrinkling of the surface is allowed. Finally, the volume of the cell is allowed to change freely, and the restrictions to passage that a real cell might experience because of its constant surface area and volume are not considered.

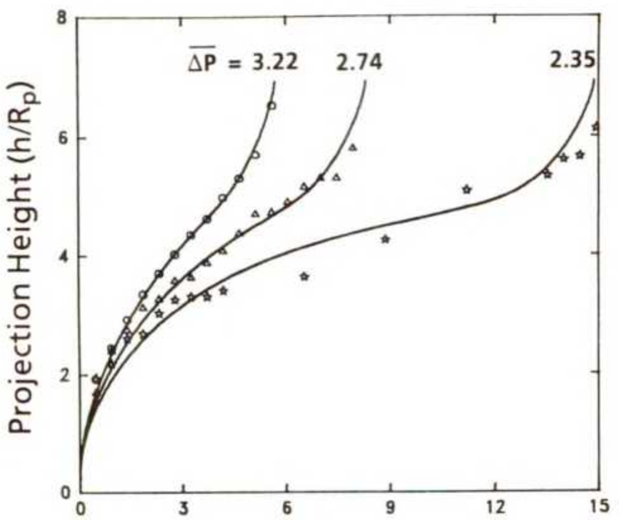

Fig 6. Three curves show the time course of the dimensionless projection height, h/R_p, at three different pressures. Solid lines show the theoretical prediction for a dimensionless cell radius, R_{Do}/R_p, of 5.0 and dimensionless pressures (from left to right), $\overline{\Delta P} = 3.22, 2.74$, and 2.35. Points represent data taken from a single cell at three different pressures: for the circles, $\overline{\Delta P} = 3.44$; for the triangles, $\overline{\Delta P} = 2.74$; and for the stars, $\overline{\Delta P} = 2.35$. The values for the dimensionless pressures for the data represent measured values. The values given for the curves were chosen to give the best agreement between the data and the theoretical curve. The 7.0% difference in the value of $\overline{\Delta P}$ for the circle data and the corresponding curve could have been due to measurement error or frictional interactions. The data were shifted vertically to allow for uncertainty in determining the zero height. The magnitudes of the shifts were 0.70 (circles), 0.54 (triangles), and 0.48 (stars). These corrections were all less than the thickness of the wafer.

RESULTS

The pore used in the present experiments was approximately 1.6 μm in diameter and 1.2 μm in thickness, as measured in the light microscope. A cell in the process of passing through the pore is shown in Fig 5. A total of 28 cells were tested. Six of these were discarded because they tended to adhere to the silicon pore and their passage times were artifactually long. The data from the remaining cells agreed well with the analytic predictions, both for the height of the projection as a function of time and for the total time as a function of the pressure difference across the pore. The sequence in which the different pressures were applied was not ordered. When a pressure was repeated for a given cell, the egress times were similar, ie, there appeared to be no history dependence of the pressure-time relationship.

Three examples of the height of the projection as a function of time are shown in Fig 6. The data were obtained from recordings of a single cell passing through the pore three different times, each time at a different pressure (0.62 mm Hg, 0.72 mm Hg, and 0.90 mm Hg). The solid lines show the theoretical prediction (Equations 3 and 4) for the projection height as a function of time for a cell with an initial radius of 4.0 μm passing through a pore with a radius of 0.8 μm at pressures of 0.62 mm Hg, 0.72 mm Hg, and 0.84 mm Hg.* Because of the finite thickness of the wafer and uncertainty about the exact location of the point, h = 0, each of the data sets was shifted vertically to minimize the average vertical distance between the data points and the corresponding curve. No other adjustments in the data or the theoretical parameters were made.

---

*The 7.0% reduction in the value for ΔP for the third curve (compared to the measured value) was chosen because better agreement between theory and data was obtained. This difference can be attributed either to measurement uncertainty or to frictional interactions between the cell and the pore.

It should be noted that not all of the measured time courses of egress agreed as well with the analytic prediction. At pressures near the threshold pressure (the minimum pressure needed to push the cell through the pore) small errors in the values chosen for R_{D_o} or ΔP resulted in large differences in the predicted time course of egress. At high pressures, the accuracy of the measurements made from the videorecordings was limited by the framing speed of the camera, and it was not possible to evaluate the accuracy of the analytic prediction. At intermediate pressures, however, the agreement between theory and observation shown in Fig 6 was typical, although in some cases the values for R_{D_o} or ΔP had to be adjusted to obtain the best fit. Considering the simplicity of the analytic model, the agreement between theory and experiment was remarkably good.

The egress times for 22 different cells over a range of pressures are shown in Fig 7. The theoretical curves are calculated for a pore radius of 0.8 μm and initial cell radii (from left to right) of 3.2 μm, 4.0 μm, and 4.8 μm. For this curve, 14 dimensionless time units correspond to one second, and one dimensionless pressure unit is 350 dyn/cm^2 (0.26 mm Hg). No parameters were used to adjust the data to fit the theoretical prediction. The agreement is again quite good, especially at the larger pressures. At very low pressures, the cells tended to pass through the pore more quickly than expected, and the actual threshold pressure was slightly lower than was predicted.

DISCUSSION

The experimental results confirm the major theoretical predictions. First, there is a threshold pressure on the order of 0.5 mm Hg required to push the cell through the pore, and second, for pressures greater than 1.0 mm Hg, passage times are typically less than one second. The accurate prediction of the change in the height of the spherical projection with time also supports the validity of the analysis and its underlying assumptions.

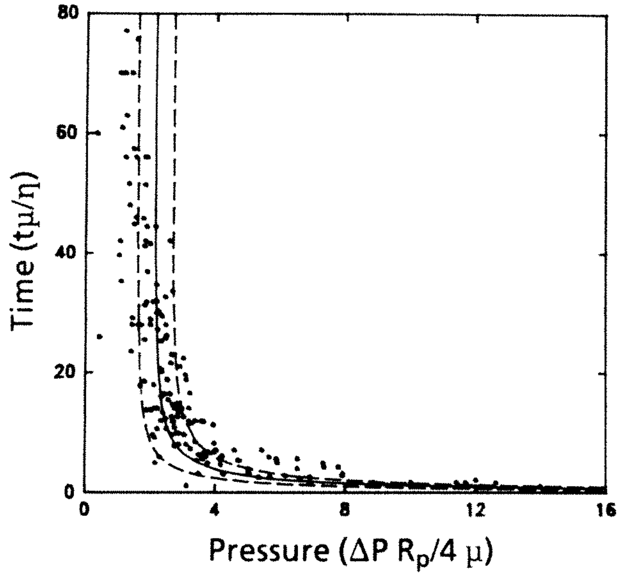

Fig 7. Egress time as a function of pressure. The dots represent all of the data taken for the 22 nonadherent cells tested. The solid curve represents the theoretical prediction for $\overline{R_{D_o}} = 5.0$; the dashed curve at the left is the prediction for $\overline{R_{D_o}} = 4.0$; the dashed curve at the right is the prediction for $\overline{R_{D_o}} = 6.0$. There were no adjustments made to obtain agreement between the theoretical curves and the experimental data.

One slight, but potentially important, difference between the analytic prediction and the experimental results is the lower-than-expected threshold pressure that was observed in the experiments. This difference is most probably due to the cell folding as it passes through the aperture. Such folding would reduce the amount of surface deformation required for passage compared to the deformation of the analytic model. It is important to recognize that because of their ability to fold, real cells can negotiate an aperture at pressures lower than that predicted by the theoretical model.

The slightly higher-than-expected passage times that were observed for pressures between 1.0 and 2.0 mm Hg are probably due to adhesive or frictional interactions between the cells and pore. Cells that took longer than expected to complete their passage generally did not follow the predicted dependence of the projection height on time. The differences between the predicted and the observed time courses were consistent with small frictional or adhesive interactions between the cell and the pore.

Constraints of surface area and volume. The present analysis does not take into account restriction on passage resulting from the conditions of constant cell surface area and volume. Although the present analysis is sufficiently accurate to predict cell passage times when the surface-to-volume ratio is sufficient for cell passage, the constraints of constant area and volume limit the size of an aperture that a cell can negotiate. The strength of this limitation is illustrated by the experimental results shown in Fig 8. A single cell was transferred with a micropipette into a series of chambers with successively decreasing salt concentrations. The pressure needed to aspirate the cell into the pipette (P_t) was measured in each chamber. Over the range of concentrations between 260 mOsm and 230 mOsm only a slight increase in P_t occurred. This slight increase was probably due to a decrease in the ability of the cell to fold, because more and more membrane area was being taken up to encompass the cell volume. The abrupt change in P_t at around 225 mOsm occurred because at this salt concentration the surface area of the cell was not sufficient to enclose the cell volume within the constraint of the pipette geometry.

Whether or not a cell is restricted from passage through a particular pore depends on the surface and volume of the cell and the size and shape of the aperture. In the Appendix a relationship is derived to calculate the minimum surface area a cell with a given volume must have to negotiate a cylindrical pore of given dimensions. In Fig 9, this minimum area is shown as a function of cell volume for three different-sized pores. The solid curve corresponds to a pore of radius (R_p) 0.8 μm and thickness (L) 1.2 μm. These are the measured dimensions of the pore used in the present study. The short-dashed curve corresponds to $R_p = 0.8$ μm and $L = 0.0$ μm. This relationship would be appropriate for the present study if the pore was hour-glass shaped, such that the thickness of the wafer at the aperture was less than the

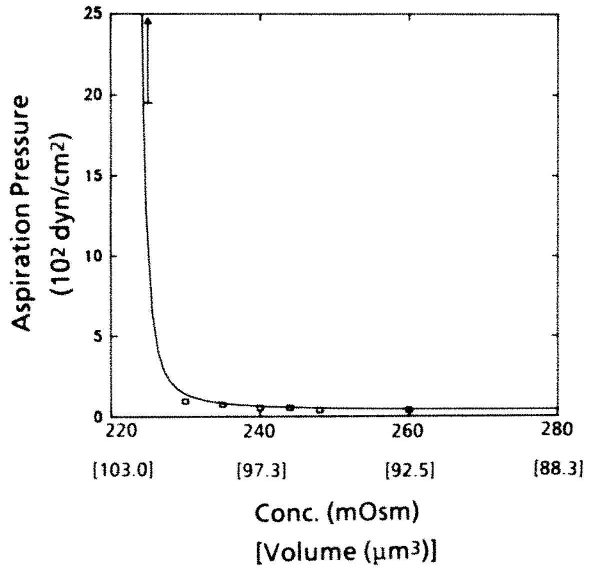

Fig 8. The pressure (P_t) required to pull a cell into a micropipette (3.5 μm ID) is shown as a function of the osmolarity of the suspending solution. Points represent measured aspiration pressures for the same cell into the same pipette in solutions of different salt concentrations. The solid curve is "hand-drawn" and has no theoretical significance. The abrupt change in P_t at around 225 mOsm occurs because the volume of the cell at this concentration is too large to be contained by the cell membrane within the constraint of the pipette geometry. The volumes shown in parenthesis were calculated based on a volume of 100 μm^3 at 230 mOsm assuming that the cell behaved as an osmometer with a nonideality coefficient of 0.6: $[(V - V_i)/V_i = 0.6\ (C_i - C)/C]$, where V_i is the isotonic volume (86.5 μm^3) and $C_i = 290$ mOsm.

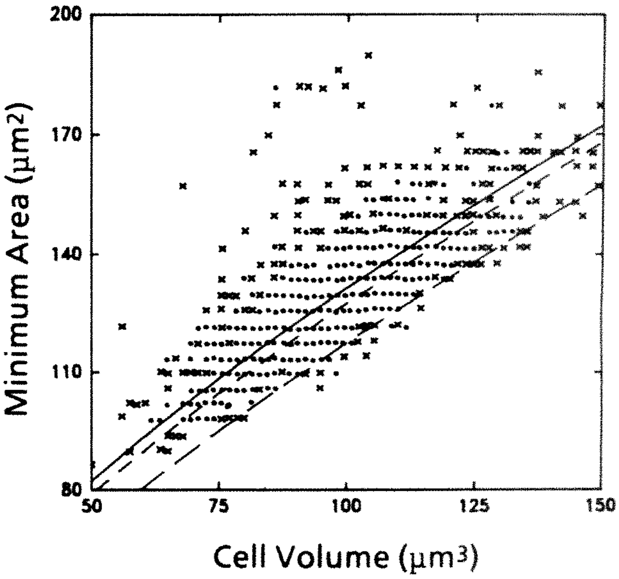

Fig 9. Minimum area required for cell passage as a function of cell volume. The solid line shows the calculated minimum area for the aperture used in the present experiments ($R_p = 0.8$ μm, $L = 1.2$ μm). The short dashed line corresponds to an aperture with $R_p = 0.8$ and $L = 0.0$. The long dashed line corresponds to $R_p = 1.6$, $L = 0.0$. The dots and X's show the range of surface areas and volumes for normal erythrocytes as measured by Tsang.[7] Each X marks a region containing an area and volume of one cell; dots indicate that more than one cell lies in that region.

thickness of the wafer at its edge. The long-dashed curve corresponds to $R_p = 1.6$ μm and $L = 0.0$ μm, a pore twice as large as the one used in the present study. During our experiments no cells were found that were incapable of negotiating the pore, indicating that all of the cells in our study had surface areas and volumes that would place them above the solid (or short-dashed) curve in Fig 9.

This observation is at odds with expectations based on the data of Tsang,[7] who used high-resolution interference holograms to measure the surface area and volume of over 1,500 cells from a variety of donors (see also Fung et al[8]). Tsang's data are shown as the shaded region in Fig 9. A significant fraction of the cells in Tsang's study lie below the minimum area curves for the pore size used in our study. Cells falling below the curve for a particular aperture should be incapable of passing through, except under very large pressures or after lysis. If the surface areas and volumes of the cells used in our study had the same surface area and volume distribution as the cells in Tsang's study, we would have expected a significant fraction of them to be unable to pass through the pore under the pressures used in our experiments. The fact that all of the cells in our study passed through was surprising.

The reason for this discrepancy is not clear. It is unlikely that it is due to an error in measuring the pore diameter, because the pore would have to have a diameter twice as large as was measured to accommodate most of the cells in Tsang's study (note the long-dashed line in Fig 9). Other explanations seem more plausible. Differences in the suspending buffers could account for at least part of the difference. (Tsang used a TRIS buffer whereas we used phosphate.) Additionally, there may have been unconscious bias in cell selection for our measurements. An earlier, less extensive study by Evans[9] using the same technique as Tsang found volumes 4.0% smaller and surface areas 4.0% larger than those reported by Tsang. This difference was thought to be due to bias in cell selection. The discrepancy between our observations and Tsang's results could be accounted for by such small differences.

Clearly, when the area of the cell is insufficient to encompass the cell volume during passage, the present analysis is inapplicable. However, as the data in Fig 8 show, when the area is sufficient, the cell volume has little effect on the dynamics of cell passage.

Implications about bone marrow egress. The results of these experiments support the feasibility of pressure-driven egress of reticulocytes from the bone marrow. Although leukocytes clearly have the capability to move themselves across an endothelial boundary, the mechanism by which reticulocytes pass into the marrow sinuses has remained obscure. Circulating reticulocytes show no evidence of intrinsic motility. If reticulocyte egress is pressure-driven, a major question remains as to the source of the pressure gradient across the pore. Two features of the present results bear on this question. The first is that the pressure required to force a cell through an aperture is small compared to systemic pressures. Michelsen[10] has measured pressure differences of 20.0 mm Hg between the marrow tissue and the emissary vein just outside the cortical bone in rabbits. It is reasonable to hypothesize that a part of that pressure drop sufficient to drive reticulocyte egress (2.0 to 4.0 mm Hg) might exist across the pore between the hematopoietic space and the marrow sinus, which is contiguous with the emissary vein.

The second feature of the present results that bears on the question of the origin of the driving pressure is the short time required to complete egress (~0.3 s) when the threshold pressure is exceeded. The pressures that Michelsen recorded were pulsatile,[10] and it is likely that pressures across the pore sufficient to cause egress, occur only transiently. Dabrowski et al[11] have shown a correlation between transient increases in marrow pressure and an increase in the release of reticulocytes into the circulation in rabbits. The fact that the times for cell passage that we have measured are less than, or on the order of, the heart rate is an important observation because it shows that if sufficient pressures for egress occur transiently with the pulse, there would still be sufficient time for egress to be completed.

It is important to recognize that in the present study we have used mature erythrocytes to develop and test our theories. If the membrane elastic modulus or the membrane viscosity of early reticulocytes were significantly different from mature cells, our conclusions might be affected. However, preliminary experiments in our laboratory on blood cells of the rabbit indicate that differences in membrane properties between mature erythrocytes and reticulocytes are slight. The average value measured for reticulocyte shear modulus of 5.5×10^{-3} dyn/cm was similar to the control value, 4.5×10^{-3} dyn/cm, and the viscoelastic recovery time constants (the ratios of the membrane viscosity to the membrane shear modulus) were also similar: 0.074 seconds for reticulocytes and 0.081 seconds for controls. The reticulocyte samples in those experiments were prepared by density gradient centrifugation. More than 90% of the cells in those samples were reticulocytes as determined by New Methylene Blue staining. However, in our experiments we selected against oddly shaped cells in favor of those that were biconcave and our data sample probably included more late than early reticulocytes. Nevertheless, it is unlikely that the properties of even very young reticulocytes are so different from mature cells that the conclusions of the present work would be affected substantially.

Our ability to critically evaluate these ideas is hampered by a lack of information about the local environment within the marrow. We have had to use pore dimensions measured in the mouse, pressure differences measured in the rabbit, and transit times and threshold pressures measured on human erythrocytes. Although differences in the architecture and hydrodynamics found within different animals may affect the details of the regulation process for each animal, the major conclusions of the present study should not be affected by anatomic differences between different species. The pressures required to move red cells across thin circular apertures are within the physiologic range, and the speed with which the passage is completed is sufficient for it to occur within the space of a single heartbeat.

ACKNOWLEDGMENT

The authors would like to thank Dr Ilesanmi Adesida and Mr Brian Whitehead of National Submicron Facility for their help and cooperation, and Dr Marshall Lichtman for his interest and encouragement, and for providing the electron migrograph shown in Fig 1.

APPENDIX

Because erythrocytes maintain essentially constant surface area and volume,[12,13] there are limits on the size and shape of an aperture that a cell can negotiate. In this appendix, a functional relationship is developed that makes it possible to calculate the maximum volume that a cell of a given surface area can have and still be able to pass through a cylindrical pore of given dimensions.

To begin the calculations, consider the shape shown in Fig 10. The surface area, A, and volume, V, of this surface of revolution are:

$$f_A = A = 2\pi\{R_1(R_1 + \sqrt{R_1^2 - R_p^2}) + R_2(R_2 + \sqrt{R_2^2 - R_p^2}) + R_pL\} \quad (A1)$$

$$f_v = V = {}^2\!/_3\pi\{R_1^3 + (R_1^2 + R_p^2/2)\sqrt{R_1^2 - R_p^2} + R_2^3 + (R_2^2 + R_p^2/2)\sqrt{R_2^2 - R_p^2} + {}^3\!/_2R_p^2L\}. \quad (A2)$$

For a fixed volume, we wish to find the relationship between R_1 and R_2 that requires the largest surface area. This is the "critical geometry" for cell passage, ie, if the cell can assume that geometry it will be able to negotiate the aperture. We use the method of Lagrange multipliers and define the function:

$$H = f_A - \lambda(V - f_v). \quad (A3)$$

where λ is the Lagrange multiplier. At the extremum three conditions must be met:

$$\frac{\partial H}{\partial R_1} = 0; \frac{\partial H}{\partial R_2} = 0; \frac{\partial H}{\partial \lambda} = 0. \quad (A4)$$

The third condition simply gives the expression for the cell volume (Equation A2). The first two conditions require that:

$$4R_1(R_1 + \sqrt{R_1^2 - R_p^2}) - 2R_p^2 + \lambda[2R_1^2(R_1 + \sqrt{R_1^2 - R_p^2}) - R_1R_p^2] = 0 \quad (A5)$$

and,

$$4R_2(R_2 + \sqrt{R_2^2 - R_p^2}) - 2R_p^2 + \lambda[2R_2^2(R_2 + \sqrt{R_2^2 - R_p^2}) - R_2R_p^2] = 0. \quad (A6)$$

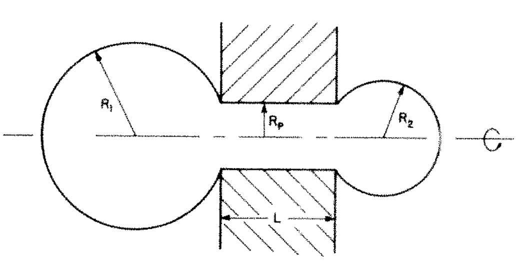

Fig 10. Schematic of a cell caught in a cylindrical aperture. The length of the aperture is L and its radius is R_p. The contours of the cell on either side of the aperture are spherical with radii R_1 and R_2.

After solving Equation A5 for λ and substituting that expression into Equation A6, it can be seen by inspection that both conditions will be met when $R_1 = R_2$. Let R_o be the outer radius when the two outer radii are equal. Then the expressions for area and volume at the critical geometry are:

$$A = 4\pi R_o (R_o + \sqrt{R_o^2 - R_p^2}) + 2\pi R_p L \qquad (A7)$$

$$V = \tfrac{4}{3}\pi[R_o^3 + (R_o^2 + R_p^2/2)\sqrt{R_o^2 - R_p^2}] + \pi R_p^2 L. \qquad (A8)$$

Equation A7 can be solved for R_o:

$$R_o = C_1 (2C_1 - R_p^2)^{-1/2} \qquad (A9)$$

where $C_1 = A/4\pi - R_p L/2$. Equation A9 can be substituted into Equation A8 to eliminate R_o and obtain a functional relationship among A, V, R_p, and L:

$$f(A, V, R_p, L) = 0 \qquad (A10)$$

To generate the curve in Fig 9, the pore dimensions R_p and L were specified, and an arbitrary value for A was chosen. R_o could then be calculated via Equation A9, and the volume, V, corresponding to the chosen value of A could be calculated directly from Equation A8. This volume is the maximum that a cell of area A can have and be able to pass through a pore of the given dimensions. Equation A10 can also be used to calculate permissible pore dimensions for cells with specified surface area and volume, but numerical techniques are required to obtain such values.

Purification of Murine Erythropoietin Produced in Serum-Free Cultures of Erythroleukemia Cells

By R.-L. Qian, K. Chin, J.-K. Kim, H.-M. Chin, J. Cone, and W.D. Hankins

We previously documented that several erythroleukemia cell lines released factors that stimulated erythropoiesis in vivo and in vitro. A simple five-step scheme has been devised that allows purification of this erythropoietic activity to apparent homogeneity. The methods employed included lectin affinity chromatography (wheat germ agglutinin), gel filtration (ultro gel ACA44), ion exchange, hydroxylapatite, and high performance liquid chromatography. Following polyacrylamide gel electrophoresis, biologic activity was recovered in an area corresponding to a molecular weight of 35,000 daltons. Silver staining of a polyacrylamide gel after electrophoresis of our most purified preparation revealed a single band at 35,000 daltons.
© 1986 by Grune & Stratton, Inc.

WE previously reported[1,2] that erythroleukemia cells derived from mice infected with Friend murine leukemia virus (F-MuLV) produced erythropoietic factors with properties similar to sheep and human erythropoietin (Epo). Subsequent studies showed that the murine Epo was active in nine separate in vivo and in vitro erythropoietic assays, and was neutralized by antibodies prepared against partially purified human Epo. While not all erythroid lines isolated from Friend virus-infected mice were positive for Epo production, four independently isolated lines made significant quantities of the hormone. We also found that Epo production by these cells continued in the absence of serum.[2] This finding has permitted us to devise a relatively simple purification scheme for the murine Epo. A five-step procedure has produced an apparently homogeneous preparation of murine erythropoietin that is active in vivo and in vitro, and has an apparent molecular weight of 35,000 daltons.

MATERIALS AND METHODS

Chromatographic materials were obtained commercially as follows: wheat germ agglutinin (Pharmacia, Uppsala, Sweden); ACA44 (LKB Instruments, Inc, Gaithersburg, Md); hydroxylapatite, fast flow (Calbiochem, San Diego, Calif). The Mono Q anion exchange resin was a part of Pharmacia's Fast Liquid Chromatography System (Uppsala, Sweden). High pressure liquid chromatography was performed on an LC-8-D8 Supelco column (15 cm × 4.6 mm).

Erythropoietin assays. Following purification by hydroxylapatite chromatography, erythropoietic activity of Epo was verified by its ability to stimulate ^{59}Fe incorporation in the polycythemic mouse assay.[3] At all other times, dose-dependent stimulation of tritiated thymidine (^{3}H-Tdr) by spleen cells from phenylhydrazine-treated mice was regarded as an index of Epo activity. Assay conditions were exactly as described by Krystal.[5]

Erythroleukemia cultures. We previously reported that several erythroleukemia lines secreted Epo.[2] The line used for the present purification of Epo was HFTC-5. HFTC-5 cells were seeded in 50 mL of medium in 150 cm Falcon flasks at two million cells/mL. The medium used was Iscove's modified Dulbecco's medium supplemented with 100 μg/mL transferrin and 100 μg/mL insulin. Cultures were incubated for 10 to 14 days and the conditioned medium monitored for Epo content with the ^{3}H-tdr assay. When the Epo level reached greater than 1 U/mL, the cells were removed by centrifugation (2,000 rpm for 5 min), and heat treated at 56 °C for one hour to inactivate the virus produced by the erythroleukemia cells. Conditioned medium was stored at 4 °C for up to one month without loss of activity.

RESULTS

Lectin chromatography. 2,000 mL of conditioned medium was applied directly to wheat germ agglutinin[4] column (2.5 cm × 27 cm; bed volume was about 100 mL) at a flow rate of 24 mL/hr. When loading was completed, the column was washed with 300 mL of PBS, following which the Epo was eluted with PBS containing N-acetyl glucosamine (0.5 mol/L). The activity and optical density (OD) profile is shown in Fig 1. Routinely, greater than 50% of the activity was recovered in a peak that trailed the second optical density peak. Specific activities for the WGA-purified material was around 27.6 U/A. The peak fractions were pooled, dialyzed against water, lyophilized, and stored at −70 °C. This material was referred to as Step I Epo. In other experiments, Epo was eluted with a gradient of N-acetylglucosamine (not shown). Neither the recovery nor the purity of Epo was improved with the gradient elution.

Gel filtration. Lyophilized Step I Epo was dissolved in 5 mL PBS (PH 7.4) and loaded onto an ACA44 gel filtration column with dimensions of 2.5 cm × 84 cm and a void volume of 130 mL. The column had been standardized with albumin (66,000 d), ovalbumin (43,500 d), chymotrypsin (25,000 d), and ribonuclease A (13,700 d). As shown in Fig 2, Epo activity was recovered between the ovalbumin and chymotrypsin peaks. The average molecular weight of the Epo peak was 35,000 to 36,000. The Epo peak was divided into three fractions referred to as head (tubes 46 and 47), middle (tubes 48–57), and tail (tubes 58–61). By pooling these three fractions, the recovery of Epo from gel filtration was in excess of 90%, a specific activity of 316.52 U/A. However, subsequent chromatographic procedures and PAGE analysis revealed that by saving only the middle portion, a high molecular protein of 66,000 (probably albumin) was virtually eliminated as a contaminant. The specific activity in this pool was 652.92 U/A (Table 1) and the recovery was 70.2%. This material was referred to as Step II Epo and was dialyzed against water, lyophilized, and stored at −70 °C.

Ion exchange chromatography. 100 to 200 units of Step II material was dissolved in water and loaded onto a mono Q anion column of Pharmacia's Fast Performance Liquid

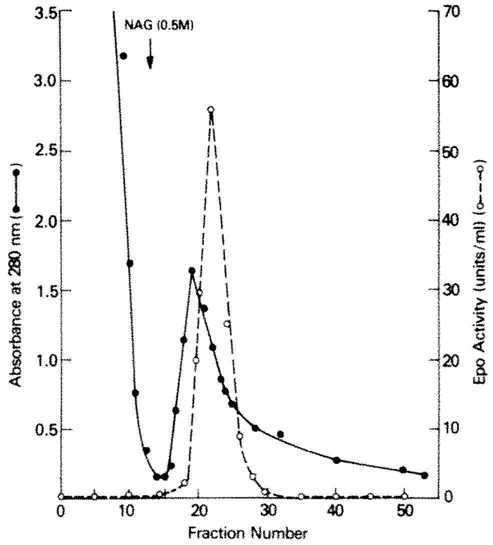

Fig 1. Affinity chromatography of erythropoietin. The serum-free supernatant of HFTC-5 cell line was applied to wheat germ agglutinin column (2.5 cm × 27 cm). Flow rate: 24 mL/hr.

Chromatography instrument. Preliminary analytical runs employing a continuous linear gradient of NaCl revealed that Epo was eluted between 0.14 mol/L NaCl to 0.25 mol/L NaCl with a peak at 0.18 mol/L NaCl. Therefore, in this and subsequent runs, the proteins were eluted with a discontinuous gradient of NaCl in a 0.01 mol/L Tris-HCl buffer (PH 7.5), as shown in Fig 3. Epo was eluted in two unequal peaks. Less than 5% of the erythropoietic activity was found in the small peak (0.1 mol/L NaCl). This material was not further analyzed. Greater than 70% of the activity was routinely recovered in 0.3 mol/L NaCl, and had a specific activity of 1,112.50 U/A. This material was dialyzed against water, lyophilized, and stored at −70 °C as Step III Epo.

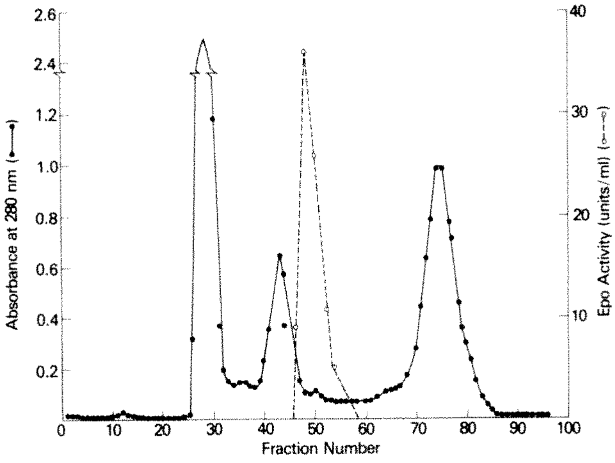

Fig 2. Gel filtration of Step I Epo on Ac44 column (84 cm × 2.5 cm). Flow rate: 5.5 mL/30 min. The column was standardized empirically using commercial molecular weight standards. The peaks albumin (67,000 d), ovalbumin (43,000 d), chymotrypsin (25,000 d), and ribonuclease (13,700 d) were recovered in fractions numbers 42, 52, 65, and 82, respectively.

Table 1. Summary of Purification of Murine EPO

Procedure	Absorbance	EPO Units	Spec Act	Fold Purified
None	11.6×10^3	2,512	0.21	—
WGA	46	1,274	27.6	131
Gel filtration	1.37	894	653	3,109
FPLC	0.56	623	1112	5,297
Hydroxylapatite	0.05	225	4500	21,000
HPLC	—*	130	—	—

Absorbance was determined at 280 mu and erythropoeitic activity was assessed by a ^{3}H-tdr uptake assay. Spec Act refers to specific activity expressed as Units of Epo/A_{280}.

*Although tested, no absorbance was detected in the HPLC-purified EPO.

Hydroxylapatite chromatography. 300 to 600 units of Step III material was added to a hydroxylapatite[6] column that had been equilibrated in 0.02 mol/L phosphate buffer, PH 6.8. A gradient of increasing phosphate concentration (0.02 to 0.1 mol/L) was employed to elute the proteins. As shown in Fig 4, three OD peaks were observed. The Epo activity profile was a symmetrical peak that overlapped the second major protein peak. The second small peak of Epo activity at fraction 29 was not reproducible and was, therefore, not included in the pooled fractions. Fractions were pooled, dialyzed, lyophilized, and stored at −70 °C as Step IV Epo. The recovery of activity from this procedure ranged between 50% and 70%.

Neuraminidase treatment and electrophoresis. To characterize the Epo purified to this stage, neuraminidase (0.06 units) was added to a solution of 100 units of Step IV Epo and dissolved in 25 μL of 50 mmol/L sodium acetate buffer, PH 5.2. This mixture was incubated at 37 °C for three hours and then boiled to destroy the neuraminidase. This material was combined with electrophoresis sample buffer, boiled for three minutes, and loaded onto a 10% polyacrylamide gel. A control preparation of Step IV Epo was similarly treated with omission of the neuraminidase. The samples were electrophoresed for four hours at a constant current of 15 mA, after which the gels were cut into 50 horizontal slices (2 mm/slice). Each slice was placed in a 12 × 75 mm glass tube to which was added 1.0 mL PBS, PH 7.4. The gel slices were mashed extensively and allowed to stand overnight at 37 °C. The following morning, the gel matrix was removed by

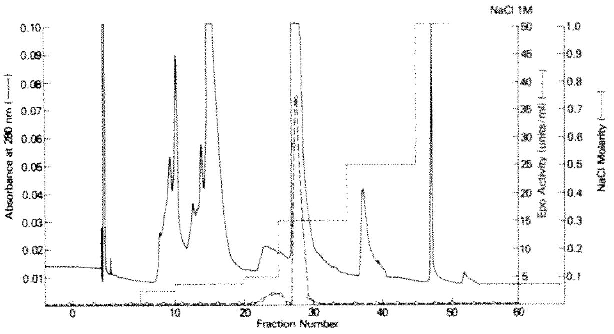

Fig 3. Ion exchange chromatography of Step II Epo on a mono Q column (5.5 cm × 1 cm). Flow rate: 1 mL/min.

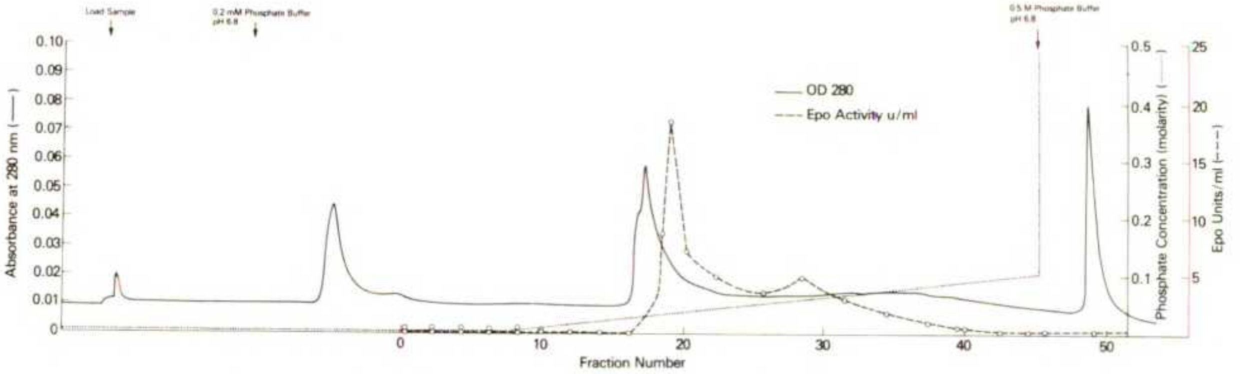

Fig 4. Purification of Step II Epo with hydroxylapatite column (1.5 cm × 5 cm). Flow rate: 2 mL/min.

centrifugation and the supernatant assayed for Epo activity. The activity profile is shown in Fig 5A. The fractions containing Epo activity were pooled, dialyzed, and again subjected to polyacrylamide gel electrophoresis (PAGE). The results, shown in Fig 5b, demonstrate that the biologic activity comigrates with a single band of silver stained material in the molecular weight range of 35,000 daltons. Yanagawa et al[7] observed that neuraminidase treatment of human Epo yielded molecules that migrated faster than nontreated Epo. As seen in Fig 5, neuraminidase-treated murine Epo also migrated slightly ahead of nontreated Epo.

High performance liquid chromatography. 200 units of Step IV material was dissolved in 0.1% TFA and applied to a Supelco LC-8-DB HPLC column. Protein was eluted with a gradient of 30% to 60% acetonitrile in 0.1% trifluoroacetic acid. More than 50% of the activity was recovered in fractions 66–68 (Fig 6). When this material was subjected to PAGE and silver stained (Fig 7), a single band of protein was recovered in a region that corresponded to 35,000 daltons. It should be noted that this gel was "overstained" in order to visualize the Epo bands. Even so, no other proteins were detected although some artifactual staining was observed in

the high molecular weight area in all lanes, including the control (lane 5), which received only the marker dye.

DISCUSSION

Discovery of multiple erythroleukemia lines that make erythropoietic growth factors provided both an opportunity and a challenge for our laboratory. First, a stable cell culture source of murine Epo has long been needed for research purposes. Second, since our findings represented the first observation of Epo production by erythroid cells, conceptual questions arose concerning the relation of Epo production to leukemic pathophysiology as well as normal red cell development. Finally, we felt that a detailed analysis of this murine erythropoietic factor might provide further insight into erythropoietin structure and function. We therefore undertook to devise a rapid and simple method, using conventional procedures that would permit isolation of homogeneous murine erythropoietin. As starting material, we used supernatants from erythroleukemia cells cultured in the absence of fetal calf serum for 10 to 14 days. Such conditioned media contained the equivalent of at least 1 U/mL of erythropoietin. The starting specific activity was 0.21 U/mg. Sequential chromatography of this material through columns of agarose-bound wheat germ agglutinin, ACA44 gel filtration matrix, ion exchange resin, hydroxylapatite, and high performance liquid chromatography has yielded a protein with erythropoietic activity in vivo and in vitro, and which produced a single band upon polyacrylamide gel electrophoresis. The apparent molecular weight of the electrophoretic band was 35,000 daltons. The overall recovery of erythropoietic activity through all the procedures was 5% to 15%. A summary of a typical purification is shown in Table 1.

Both human and sheep erythropoietin have been reported to be glycoproteins.[4,6-8] Our finding that neuraminidase treatment of hydroxylapatite purified material increased the electrophoretic mobility of the erythropoietic activity and abolished the in vivo activity[2] are consistent with the interpretation that murine erythropoietin is also a glycoprotein.

The data in this report provide further support for our contention that the eythropoietic factors produced by the erythroleukemic lines are indeed erythropoietin.[1,2] Since human Epo is the only erythroid regulatory factor that has been purified, sequenced, and molecularly cloned,[8] it seems an appropriate molecule for comparison. Our previous results[1,2] and those of Choppin et al[3] demonstrated many similarities between human Epo and the factors produced by erythroleukemia cells. For example, all the physical and chemical properties assessed for murine and human Epo have been identical.[1-3] Furthermore, we demonstrated immunologic cross-reactivity between murine Epo and antisera raised against human Epo.[2] Since the reported molecular weight of human Epo is approximately 35,000[6] we can now include molecular weight amongst the similarities between murine and human Epo. Nevertheless, for a complete comparative analysis, the amino acid sequence and the nucleic acid sequence of the corresponding genes will be necessary. Experiments to derive this additional information are presently underway.

Erythropoietin, an Autocrine Regulator? Serum-Free Production of Erythropoietin by Cloned Erythroid Cell Lines

By W. David Hankins, John Schooley, and Christina Eastment

Production of lymphoid and myeloid growth regulatory factors by hematopoietic cells is well documented. On the other hand, the major site of production of erythropoietin (Epo), which regulates physiologic red blood cell development, is thought to be the kidney. Here we report the isolation of multiple erythroleukemia cell lines that produce erythropoietic factors and present extensive biological, immunologic, and biochemical evidence to document that the active agent is Epo. The erythropoietic activity was neutralized by Epo antiserum and exhibited physical properties indistinguishable from those of human and sheep Epo. Positive lines produced between 0.1 and 1.5 U/mL of Epo, which stimulated erythropoiesis in vivo and in vitro in nine biological assays. Twenty sublines derived from single cells were inducible for hemoglobin and spectrin synthesis. All the sublines produced Epo. Production of the hormone continued when the cells were seeded in the absence of serum. Our finding that multiple independent isolates produce Epo raises the possibility that Epo production by erythroid precursors may play a role in normal erythropoiesis or, alternatively, that Epo gene activation may be a relatively common occurrence that contributes to, or is associated with, certain forms of virus-induced leukemias.

GROWTH AND DIFFERENTIATION of blood-forming elements are influenced by a family of diverse molecules, referred to collectively as hematopoietic regulators. Although their in vivo roles are poorly defined, these regulators clearly have proliferative or differentiative actions on specific target cell populations in the various hematopoietic lineages. Although produced in vitro by a variety of cell types, the in vivo site of synthesis for most hematopoietic regulators is unknown. Erythropoietin (Epo), a glycoprotein hormone, appears to be the exception to these statements, since numerous in vivo and in vitro experiments have demonstrated that an in vivo role of this hormone is in the regulation of red cell development.[1,2] Furthermore, while limited in vitro production of Epo has been observed, it is generally held that the major in vivo site of production of this hormone is the kidney, although extrarenal production has been documented.

During recent attempts to isolate new erythroleukemia lines from Friend virus-infected mice, we made several observations that led us to suspect that Epo might be produced by erythroid cells. First, transplantable erythroleukemia cells grew better at high density than at low density, and addition of Epo or conditioned media from an established erythroleukemia line stimulated growth of these primary cultures.[3] Second, the conditioned medium also stimulated hemoglobinization of erythroid bursts induced in vitro by the anemia-inducing strain of Friend virus complex. Third, when tested for tumorigenicity in nude mice, IW32 erythroleukemia cells[4] induced a polycythemia concomitant with tumor formation (D. Hankins and P. Tambourin [Pasteur Institute, Paris], unpublished observations, December 1982).

We therefore isolated and screened numerous erythroleukemia lines for production of erythroid growth factors. We report here the identification of three erythroid cell lines that secrete erythropoietic factors that are active in vivo and in vitro and have biochemical, immunologic, and physical properties identical to those of erythropoietin. Clones of Epo-producing cells were derived, characterized as erythroid cells, and shown to produce Epo in the absence of serum. A companion paper in this issue describes purification of this murine Epo to apparent homogeneity.

MATERIALS AND METHODS

Derivation of erythroleukemia lines. H-11 and the uncloned HFTC lines were derived on different occasions from liver or spleen explants prepared from separate Friend murine leukemia virus[5]-infected mice (W.D.H., unpublished observations, March 1980 and February 1981). Procedures used to induce erythroleukemia and establish permanent cell lines were as described by Oliff et al.[6] In an attempt to induce de novo generation of spleen focus-forming virus (SFFV), we exposed HFTC cells to 5-azacytidine as described by Graf et al.[7] The cells that survived (<10%) were cloned and frozen. Several clones were screened for SFFV production and were uniformly negative. Because of subsequent observations, several HFTC clones were retrieved and screened for the production of erythroid growth factors. MELC-FVA-28 and MELC-FVP-16 were established from mice infected with the anemia (FVA) or polycythemia (FVP) strains of Friend virus complex, respectively, as described by Mager et al.[8] TP-3 was originally isolated and characterized as an erythroleukemia line by Oliff et al.[6] IW32, another transplantable erythroleukemia line, was isolated and introduced to our laboratory by Dr Pierre Tambourin as previously described.[4] All transplants were in NFS/N or NIH nu/nu mice, which were obtained from the National Institutes of Health small-animal facility in Bethesda, Md.

Erythropoetic assays. Erythropoietic assays were standardized, using Connaught (Toronto) Step III Epo. CFU-E and BFU-E erythroid colony assays in semisolid media were performed as described.[9-11]

For ^{59}Fe uptake assays, hematopoietic cells were cultured in 0.8% methylcellulose containing 30% fetal calf serum (FCS) for two days, as previously described.[12] Twenty-four hours before harvest, $^{59}FeCl_2$ was added to 1 μCi/mL. After the 24-hour pulse, cells were harvested and the ^{59}Fe incorporated into heme was assessed.[12] The in vivo polycythemic mouse assay was performed as previously described.[13] The tumorigenicity assay was performed by subcutaneous inoculation of NIH nu/nu mice with 0.2 mL of Dulbecco's

minimum essential medium (D-MEM) containing 5 × 10^6 erythroleukemic cells. Animals were observed during the subsequent four months for tumor formation. Hematocrits were determined in 20 μL microhematocrit tubes (Drummond) on each mouse in which subcutaneous tumors developed. Tritiated thymidine (^{3}H-tdr) incorporation assays were performed as described by Krystal.[14]

Virus assay. The SFFV assay was performed as described by Axelrad and Steeves.[15]

Antibody neutralization of erythropoietin. Preparation of the erythropoietin antiserum used in these experiments was described by Schooley and Garcia.[16] Goat antirabbit IgG was purchased from Cappel Laboratories, Malvern, Penn.

Chemicals and enzymes. Neuraminidase, trypsin, ribonuclease, deoxyribonuclease, and ammonium sulfate were purchased from Calbiochem (San Diego). Treatment of conditioned media with neuraminidase and trypsin was as described previously.[17] To assess nuclease sensitivity of the erythropoietic factors, 1 μg/mL of either ribonuclease or deoxyribonuclease was added to conditioned media and incubated for one hour at 37 °C. In control experiments, similar incubations of these enzymes rendered RNA and DNA (100 μg/mL) completely soluble in 10% perchloric acid after one hour of incubation at 37 °C.

Serum-free culture. HFTC-5 cells were grown in D-MEM containing 10% FCS to a density of 2.0 × 10^6 cells per milliliter. Cells were collected and seeded at 2 × 10^6 cells per milliliter in Iscove's modified D-MEM containing insulin (1 μg/mL) and transferrin (1 μg/mL). Such cultures were incubated for 14 days at 37 °C. After removal of the cells by centrifugation, conditioned media were filtered through a 0.45-μm filter and stored at 4 °C.

Single-cell cloning. The indicated cell lines were seeded in D-MEM + 10% FCS in 96-well microtiter dishes (0.1 mL per well), with each well containing an average of 100, 10, 1, or 0.1 cells per well. After one week of incubation, each well was screened microscopically. Wells containing an estimated 64 to 128 cells were marked as potential single-cell clones, based on an observed doubling time of 18 to 24 hours. After a further week of growth, ten such clones were transferred to 1-mL dishes and expanded. Each of the ten clones was then subjected to another cycle of single-cell cloning, and second-cycle clones were picked and expanded, and tested for Epo production.

RESULTS

Screen of hematopoietic cells for erythroid growth factors. At least three virus preparations have been isolated from the origional virus stocks isolated by Dr Charlotte Friend.[18] Each of these preparations induces a qualitatively distinguishable form of erythroleukemia (for review, see ref. 19). One stock contains only a single replication-competent helper murine leukemia virus (F-MuLV) and appears to induce a rapid erythroleukemia when injected into newborn NIH Swiss mice. Two stocks, FVA and FVP, are complexes containing the anemia- or polycythemia-inducing form of SFFV in addition to F-MuLV. These complexes induce a profound erythroblastosis within two to three weeks after inoculation of either adults or newborns. We and others have isolated a number of cell lines from the erythroleukemias induced by each of these viruses. Due to the preliminary observations described earlier, we screened numerous murine cell lines for erythroid growth factors. In our initial screen we tested the ability of various conditioned media to stimulate hemoglobin synthesis by cultured fetal liver cells.[20] Of 12 FVP lines, nine FVA lines, and nine F-MuLV lines tested, only four produced detectable erythroid growth factors (Table 1). The positive lines, HFTC (subclones 5 and 14), IW32, H11, and TP-3, were all derived from F-MuLV-infected mice.

We next tested media from two human erythroleukemia[23,24] and two chemically induced rat erythroleukemia lines.[22] No erythroid activity was detected in supernatants from any of these lines.

Biological actions of murine erythroleukemia cell conditioned media. The ^{59}Fe assay can be influenced by factors other than Epo,[25] and changes in specific activity of ^{59}Fe could possibly explain the apparent stimulation of hemoglobin. We therefore tested the media for erythropoietic activity in five additional assays in vitro and three different in vivo assays (Table 2). The media from HFTC-5 and TP-3 were active in all nine biological assays. We observed that media from HFTC-5 and TP-3 produced dose-response curves similar to those of Connaught Step III Epo in at least two of the nine assays (results not shown). We conclude that while each of the individual assays may have deficiencies, the collective data from nine erythropoietic assays provide compelling evidence that the biological actions in media from HFTC-5 and TP-3 cultures were identical with those of erythropoietin. Conditioned media from HFTC-5 and TP-3 were tested for interleukin 3 activity, and they were negative (J. Ihle, personal communication, February 1983). Neither media could substitute for Wehi conditioned media as a source of burst-promoting activity (BPA)[11] in a mixed erythroid colony assay (not shown). Finally, TP-3 and

Ten microliters of test sample was added to 0.10-mL cultures of 12- to 13-day fetal liver cells[20] and ^{59}Fe incorporation assayed 48 hours later as described.[12] Epo content was estimated by comparison to a standard curve generated with Connaught step III Epo. In our hands, this assay reproducibly detects the equivalent of 10 mU of Epo per 0.1-mL culture. Therefore, media containing more than 100 mU/mL would register positive. ^{59}Fe incorporation determined as described by Filmanowicz and Gurney.[13] The lower limit of detection in this assay is an Epo concentration of 50 mU/mL. ND, not done.

In assays 1 through 4, standard Epo was added at a final concentration of 0.25 U/mL. HFTC-5 and TP-3 conditioned media (4-day harvest) were assayed at a final concentration of 10% vol/vol. In assays 5 and 6, the final concentration of standard Epo was 2.5 U/mL and conditioned media were concentrated tenfold (Amicon filtration) before use in the assay at 10% vol/vol. In assays 7 and 8, 0.25 units of standard Epo or 1 mL of conditioned media was injected subcutaneously into plethoric mice.[13] In assay 7, all samples were coded samples and were assayed "blind" by J.S. In assay 8, we tested whether inoculation of 1.0 mL of media into polycythemic mice[13] produced morphologically identifiable erythroblasts 48 hours later. In assay 9, we tested whether HFTC-5 and TP-3 were tumorigenic in nude mice and if so, whether tumor-bearing mice exhibited polycythemia. Cells (2 × 10^6) from each line were inoculated subcutaneously into three NIH nu/nu mice at 4 weeks of age. Controls were given a single injection of phosphate-buffered saline. Animals inoculated with HFTC-5 and TP-3 exhibited subcutaneous tumors eight weeks postinoculation. At this time, blood was collected from the tail and hematocrits (% packed cell volume) determined. The observed increase in hematocrits appeared to be due to increased red cell production, since no changes in the thickness of the white blood cell layer (buffy coat) were observed.

HFTC-5 media were unable to stimulate the growth of granulocyte-macrophage (GM) colonies, and therefore were presumably devoid of GM colony-stimulating factors.[26]

Neutralization of erythropoietic activity by anti-erythropoietin antiserum. Table 3 presents evidence that the erythropoietic activities in the media from HFTC-5 exhibited immunologic properties of Epo. Antiserum from rabbits that had been immunized with human urinary erythropoietin was previously shown to neutralize endogenous mouse Epo.[16,27] Conditioned media from HFTC-5 were mixed with this antiserum for a 30-minute incubation, after which goat antirabbit gamma globulin (GARGG) was added and the immune precipitate removed by centrifugation.[27] This approach was chosen instead of the alternative method of direct inoculation of the antiserum into the mouse without prior exposure to the hormone. Our rationale was that the erythropoietic agent in conditioned media might not be Epo, but only an enhancer or inducer of endogenous Epo. If such were the case, in vivo inoculation of antiserum would still abolish the erythropoietic activity. Because neutralization was accomplished in vitro before inoculation, we can conclude that the erythropoietic agent in the conditioned media is immunologically similar to Epo. That antigen–antibody interactions were responsible for the neutralization (rather than some other nonspecific inactivation by other agents in the antiserum) was indicated by our finding that pretreatment of the antiserum with GARGG abolished its Epo-neutralizing activity (Table 3). Three other immunology observations are relevant (data not shown). First, 0.3 to 0.8 U/mL of Epo has been detected in HFTC-5 conditioned media by radioimmunoassay. Second, the Epo antiserum recognized and neutralized erythropoietic activity recovered from the 43- to 45-kd area after gel filtration (see Fig 1) on Sephacryl S200. Finally, conditioned media from TP-3 and IW32 were also neutralized by this antisera. Collectively, these data indicate that the erythropoietic agent produced by these murine lines shares antigenic properties with human erythropoietin.

Physical properties of erythropoietic factors. To further assess the properties of these erythropoietic factors, conditioned media from HFTC-5 and TP-3 were tested after exposure to a variety of physical and enzymatic treatments (data not shown). The agent responsible for erythroid stimulation was stable to heat treatment (56 °C for one hour and boiling for five minutes), dialysis (molecular weight [mol wt] cutoff 30 kd), and more than five freeze-thaw cycles. Exposure of the conditioned media to degradative enzymes revealed that more than 90% of the in vivo[13] erythropoietic

Table 3. Neutralization of Erythropoietic Activity Produced by HFTC-5 by Erythropoietin Antiserum

Treatment	^{59}Fe Uptake in Polycythemic Mouse Assay (%)
Uninjected	0.08 ± 0.01
Normal rabbit serum + HFTC-5 media + GARGG	15.00 ± 1.47
Epo-antiserum + HFTC-5 media + GARGG	0.70 ± 0.28
(Epo-antiserum + GARGG), then + HFTC-5 media	9.40 ± 1.70

Rabbit erythropoietin antiserum[17] (0.2 mL) was added to 6 mL of test media and incubated at 37 °C for 30 minutes after which 0.5 mL of goat antirabbit gamma globulin (GARGG) was added. After further incubation at 37 °C for 30 minutes, precipitates were removed by centrifugation at 5,000 rpm for ten minutes. One milliliter of the supernatant was injected subcutaneously into plethoric mice. Two days later the mice received 1 µCi ^{59}Fe (ICN). Seventy-two hours subsequent to injection of the isotope, 0.5 mL of blood was removed and the percentage of ^{59}Fe uptake determined.[23] Standard error of the mean, six mice per assay.

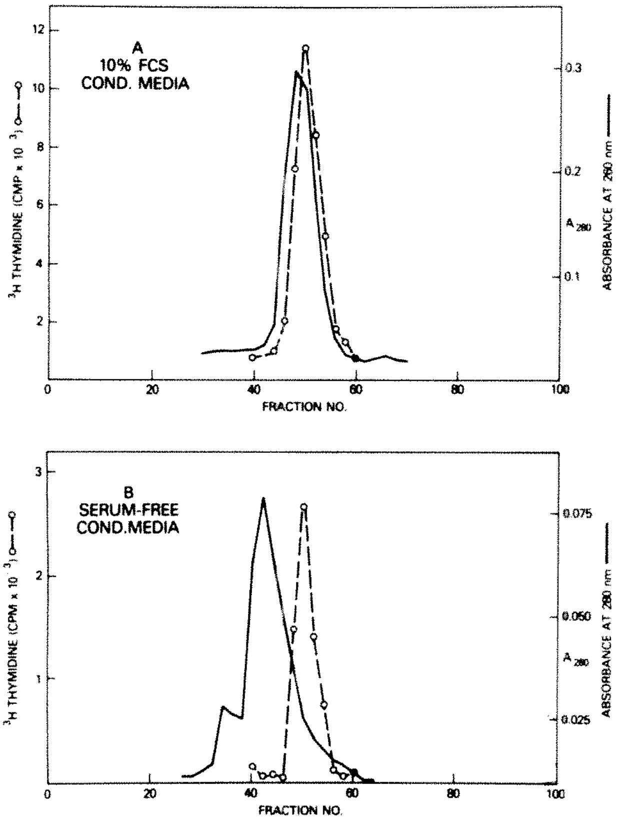

Fig 1. Gel filtration of HFTC-5 conditioned media. Conditioned media was prepared in the presence (A) or absence (B) of serum as described in Materials and Methods. Gel filtration was performed on Sephacryl S200 (79 × 2.5 cm). Fractions were tested for erythropoietic activity in the ^{3}H-tdr assay. When precalibrated at a flow rate of 1 drop per second, albumin (67,000 daltons) and ovalbumin (43,500 daltons) were recovered in fractions 43 and 53, respectively. The peak of erythropoietic activity was recovered between 43 and 45 kd in both (A) and (B).

activities were destroyed by trypsin and neuraminidase[17] but not by ribonuclease or deoxyribonuclease. On ammonium sulfate fractionation, more than 90% of the erythroid stimulating activity was precipitated at salt concentrations between 50% and 80% of saturation. Thus, in all cases, the murine erythroid factors exhibited physical properties indistinguishable from those reported by others for sheep and human Epo.[1]

Erythropoietic activity in TP-3 and HFTC-5 is not a virus. Because these cell lines were isolated from Friend virus-infected mice, an infectious virus might be the erythropoietic agent. However, erythropoietic activity was not removed from conditioned media of HFTC-5 and TP-3 by a centrifugation that pellets RNA tumor viruses (100,000 g for two hours[28]) (data not shown). Furthermore, the heat stability, mol wt estimates, enzyme sensitivity, and antibody neutralization studies are not consistent with the notion that the erythropoietic agents are RNA tumor viruses.

Production of erythropoietin by cloned erythroleukemia cell lines. Because HFTC-5 and TP-3 were independently derived from mice with Friend erythroleukemia, a high percentage of the cells resemble basophilic erythroblasts when stained with Wright's stain, and are lightly positive for spectrin,[6] it was considered likely that the cells making Epo were erythroid cells. However, because the cells were heterogeneous with respect to size and morphology, we have sought more rigorous evidence that the cells that secreted Epo were the same as cells with erythroid potential. A series of subclones was derived by two cycles of single-cell cloning and tested for Epo production and their potential to undergo terminal erythroid differentiation. Table 4 shows that every subclone of HFTC-5 and TP-3 produced Epo. In this experiment, the amount of Epo varied from 0.14 U/mL to 5.2 U/mL. It should be emphasized that the harvests in this experiment were random collections. Experiments are in progress to determine whether the level of production of a particular subclone is stable with passage. The table also shows that in the 20 subclones tested, all were positive for spectrin and were induced to differentiate by incubation in hemin.

Production and assay of Epo in serum-free cultures. Our attempts to grow HFTC-5 cells in serum-free culture have thus far been unsuccessful (C.E. has preliminary evidence that one clone of IW32 cells proliferated and produced Epo in serum-free media). In the present study, Epo continued to accumulate in cultures maintained for ten days in the absence of serum. Clone HFTC-5d (see Table 4) was seeded at 2 × 10^6 cells per line in Iscove's modified Dulbecco's medium supplemented only with 5 μg/mL trans-

Random harvest of conditioned media was assayed in the tritiated thymidine uptake assay as described by Krystal.[14] More than 50% of the cells reacted with benzidine and with anti-spectrin antibody after four days' culture in medium containing 5 × 10^{-5} mol/L hemin.

ferrin and 5 μg/mL insulin. Assays of conditioned media collected on days 2, 4, and 10 gave Epo values of 0.22, 0.47, 0.86 U/mL in vitro and 0.10, 0.53, and 0.75 U/mL in vivo, respectively. Addition of 1% bovine serum albumin or increasing the level of transferrin or insulin did not lead to higher Epo levels.

When conditioned media were subjected to gel filtration, the in vitro erythropoietic activity was recovered between 43 and 45 kd whether the cells were cultured in the presence or absence of serum (Fig 1). The optical density profile, however, was quite different and indicated that gel filtration of serum-free material provided substantial purification of Epo from the bulk of the protein. These observations suggest that this murine Epo is secreted in a mature form and does not require modification or activation by serum factors.[29]

DISCUSSION

We previously reported[4] that an erythroleukemia cell line, identified by Dr Pierre Tambourin, released erythroid growth factors. In this report, we have attempted to extend our earlier observations by addressing four questions. (1) Is erythropoietin production a universal property of erythroid leukemia cell lines? (2) Is the erythropoietic factor erythropoietin? (3) Can erythropoietin be produced in serum-free cultures? (4) Are the factor-producing cells, indeed, erythroid?

We have now screened more than 70 murine erythroleukemia lines for production of erythroid growth factors. Four positive lines have been identified. HFTC-5, TP-3, and IW32 have consistently produced the highest quantity of Epo. It is interesting that all the positive lines were isolated from leukemic mice that had been infected with a replication-competent murine leukemia virus biologically cloned from Friend virus stocks. When inoculated into newborn NIH Swiss mice, F-MuLV induces a rapid erythroproliferative disease that culminates in splenomegaly, anemia, and death in 100% of the animals.[5] However, weekly transfusion of red blood cells when severe anemia develops leads to apparent amelioration of the symptoms and survival of the mice.[6] Three to 12 months after cessation of the transfusions, approximately half the mice again develop splenomegaly and anemia and, ultimately, die of leukemia. Intravenous inoculation of spleen cells from the relapsing mice revealed transplantable leukemic cells that produce fatal leukemia. From such transplantable leukemias, permanent erythroid lines have occasionally been established in culture, and as we report here, some but not all of these lines produce Epo. Thus far we have found three of eight lines to be positive, whereas our French collaborators have detected Epo production by two of five lines (P. Tambourin, personal communication, July 1985). Therefore, production of Epo at high levels (>0.1 U/mL) is not an invariant property of F-MuLV–induced erythroleukemia cells. Furthermore, none of the other virus-induced or chemically induced erythroleukemias or human erythroleukemia cell lines produced the hormone. Therefore, we can conclude that the production of Epo is not a universal property of erythroleukemia cell lines.

In the absence of the amino acid sequence of murine erythropoietin, we cannot unequivocally establish that this erythropoietic factor is a single molecular entity. Nevertheless, the erythroleukemia factor specifically stimulated erythropoiesis in nine distinct assays and was physically, biochemically, and immunologically indistinguishable from commercial sheep plasma Epo and human urinary Epo. Gel filtration, dialysis, and antibody neutralization data argue against the possibility that the erythropoietic activity is a prostaglandin, or cyclic adenosine monophosphate, or cyclic guanosine monophosphate, which have also been reported to influence erythropoiesis.[2] Therefore, we conclude that the erythropoietic molecule released by HFTC-5 and TP-3 is mouse Epo. Additional support for this conclusion comes from our purification studies (this issue) and studies by Choppin et al.[30]

Our correlation of Epo production with induction of benzidine-reactive material and spectrin in 20 cloned lines and our morphology studies all indicate that HFTC-5 and TP-3 cells are in fact erythroid precursors. We cannot, however, rule out the possibility that the clones were bipotential and could give rise to a small percentage of non-erythroid progeny.

The production of a red blood cell regulator by erythroid progenitors was an unexpected finding. Two explanations for this phenomenon may be suggested. First, since all the positive lines were derived from F-MuLV–infected mice, Epo production may be uniquely related to the pathology of F-MuLV disease. For example, insertion of all or part of F-MuLV or another virus may activate the erythropoietin gene or a regulatory gene that influences transcription of the Epo gene. Given the relatively high percentage of positive lines, such a finding would suggest the existence of preferred integration sites or "hot spots."

Second, it is possible that normal erythroid precursors may transiently secrete Epo at a certain stage of differentiation, and that HFTC-5, H-11, TP-3, and IW32 may represent erythroid progenitors "selected" at this stage. Although we have no information regarding the target cells for F-MuLV, earlier studies have indicated that the target cells for SFFV-induced erythroid transformation in vitro are confined to a relatively narrow window of erythroid differentiation. Thus, it is possible that F-MuLV provides a growth advantage (transforms) for erythroid precursors at a stage of differentiation in which transient autocrine production of Epo is part of normal development. According to this thesis, the Epo-negative lines would be presumed to have been transformed by F-MuLV at an earlier or later stage of differentiation. Lotem and Sachs,[31] on the basis of studies with transformed myeloid cells, suggested that the production of myeloid differentiative factors might be associated with normal myeloid differentiation. Others[32,33] have associated autocrine production of hematopoietic factors with the leukemic phenotype.

ACKNOWLEDGMENT

We express appreciation to Dr Pierre Tambourin for his open collaboration during the early phase of this work. We also thank Judi Luna, Brian Fletcher, and Kay Chin for valuable technical assistance.

A New Variant of Type II von Willebrand Disease With Aberrant Multimeric Structure of Plasma but Not Platelet von Willebrand Factor (Type IIF)

By Pier Mannuccio Mannucci, Rossana Lombardi, Augusto B. Federici, Judith A. Dent,
Theodore S. Zimmerman, and Zaverio M. Ruggeri

A patient with a lifelong bleeding disorder was diagnosed as having Type II von Willebrand disease. The larger multimers of von Willebrand factor were absent from her plasma but present in platelets. A high-resolution electrophoretic technique was used to study the complex structure of individual von Willebrand factor multimers. In normal plasma, each multimer could be resolved into five bands: a more intense central one and four less intense, two moving faster and two slower than the central band. In normal platelets, each multimer could also be resolved into five bands. The central one had a mobility similar to that in plasma, whereas the four satellite bands had a mobility that differed from that of the corresponding plasma bands. In the patient, platelet von Willebrand factor antigen content and ristocetin cofactor activity were normal, and von Willebrand factor showed the same structure of individual multimers as seen in normal platelets. On the other hand, plasma von Willebrand factor antigen and ristocetin cofactor activity were decreased, and the structure of individual von Willebrand factor multimers was different from that of normal plasma and similar to that seen in normal and patient's platelets. After infusion of 1-deamino-8-D-arginine vasopressin, the largest von Willebrand factor multimers, as well as new satellite bands with a mobility similar to those in normal plasma, appeared in the patient plasma, and the levels of von Willebrand factor antigen and ristocetin cofactor activity became normal. Yet no relevant change in the prolonged bleeding time was observed. This new variant of von Willebrand disease, therefore, is characterized by the presence of a dysfunctional von Willebrand factor molecule that exhibits unique structural abnormalities in plasma but appears to be normal in platelets. The designation of Type IIF is proposed for this type of von Willebrand disease in accordance with the terminology that has been previously used.

©1986 by Grune & Stratton, Inc.

ANALYSIS OF THE MULTIMERIC STRUCTURE of von Willebrand factor (vWF) has proved essential for a more precise characterization of the molecular abnormalities of this glycoprotein in patients with von Willebrand disease.[1,2] Improvement in the electrophoretic resolution of the structural organization of individual vWF multimers[3,4] has recently been accompanied by the identification of new variant forms of von Willebrand disease.[4-9] It is apparent that the survey of large numbers of patients using refined analytical methods will lead to a better characterization of the congenital molecular defects of vWF and will help to explain the significance of the complex multimeric structure of this protein.

In this study we have used an improved high-resolution electrophoretic technique recently developed by some of us,[4] to define the structural vWF abnormality in a new variant form of Type II von Willebrand disease. The patient described here had a lifelong bleeding disorder and lacked the largest vWF multimers in plasma. These were present in platelets, however, and appeared in the circulation after administration of 1-deamino-8-D-arginine vasopressin (DDAVP). Moreover, the complex banding pattern of each multimer was distinctly aberrant in the patient's plasma but normal in her platelets. In keeping with terminology that has been previously used,[1,3-9] this new variant form has been designated Type IIF von Willebrand disease.

MATERIALS AND METHODS

Patient. The propositus was a 55-year-old Caucasian female who was referred to the Angelo Bianchi Bonomi Center in Milan, Italy, in March 1983 because of excessive bleeding during hysterectomy for fibromyoma. A lifelong history of easy bruising, epistaxis, and menorrhagia was reported. Two dental extractions had been accompanied by excessive bleeding five years before referral, but appendectomy and cholecystectomy were carried out without bleeding complications at ages 31 and 45, respectively. The mother, a brother, and a sister of the propositus did not report any bleeding tendency. The father died five years before our evaluation and had no history of bleeding. In May 1983, a surgical procedure was deemed necessary to correct a vaginal fistula diagnosed in the propositus. She was hospitalized and treated with DDAVP and cryoprecipitate to correct her bleeding tendency. DDAVP was also given subsequently on several occasions for experimental purposes. Informed consent was obtained from the patient and all normal controls before performing any experimental procedure, according to the Declaration of Helsinki.

Experimental procedures. The bleeding time was measured by performing two 1-cm long × 1-mm deep incisions in the forearm skin, using a template device (Simplate II, General Diagnostics, Morris Plains, NJ).[10] Blood was drawn from an antecubital vein, through a 19-gauge needle, into a polypropylene syringe and immediately transferred into polypropylene tubes containing 1/10th final volume of 0.129 mol/L trisodium citrate. The anticoagulant also contained protease inhibitors, namely, EDTA, *N*-ethylmaleimide, and leupeptin (Chemicon, El Segundo, Calif) to give final blood concentrations of 5 mmol/L, 6 mmol/L, and 1 mmol/L, respectively. Platelet-rich plasma was prepared by pooling the supernatants from three successive centrifugation steps, each performed at

1,100 g for 45 seconds at room temperature (22 to 25 °C). Ristocetin-induced platelet aggregation (RIPA) was measured with graded amounts of ristocetin (Sigma Chemical Co, St Louis) as previously reported.[11] Platelet-poor plasma was prepared by centrifugation at 3,000 g for 20 minutes at 4 °C. It was then rapidly separated from the sedimented cells and either used for assay the same day or stored at −70 °C until tested. When necessary, frozen plasma was transported in dry ice. Factor VIII procoagulant activity (VIIIC) was assayed by a one-stage clotting technique[10]; vWF antigen by electroimmunoassay[10]; and the ristocetin cofactor activity of vWF, using formalin-fixed platelets.[12] Concentrations of these three activities were expressed in international units (IU) per deciliter, referred to pooled normal plasma calibrated against the First International Reference Preparation for Factor VIII-Related Activities in Plasma (National Institute for Biological Standards and Control, London). The activity of "average" normal plasma corresponds to 100 IU/dL. Platelets were counted in blood collected in EDTA, using phase contrast microscopy.[13]

Electrophoresis of vWF in agarose gels containing sodium dodecyl sulfate (SDS) was performed as previously described,[3] with the following modifications. Short gels were 22 cm wide × 9 cm long × 1.5 mm thick and were cast using either 1.2% high-gelling temperature agarose or 1.4% low-gelling temperature agarose (Sigma) on Gel Bond film (FMC Corp, Rockland, Me). The gels were allowed to polymerize at 4 °C for three hours before the pouring of the stacking gel, 2.5 cm long, consisting of 0.8% high-gelling temperature agarose (FMC). Ten sample wells, each 10 × 2 mm, were cut 1 cm from the stacking-resolving gel interface, and 20-μL samples were applied. Electrophoresis was performed horizontally, at a constant current of 0.41 mA/cm and constant temperature of 16 °C, in an LKB Multiphor apparatus (LKB, Pleasant Hill, Calif) until the tracking dye was 0.5 cm from the anodal wick (usually 18 hours). Long gels were 14 cm wide × 29 cm long × 1.5 mm thick and were cast using 2.2% low-gelling temperature agarose on Gel Bond kept between glass plates. The stacking gel was poured around an eight-well Teflon comb. Samples, 25 μL containing 30% glycerol, were applied into the wells. Vertical electrophoresis was performed in a Hoefer Scientific (San Francisco) SE 620 apparatus at 0.75 mA/cm across the gel for 18 hours or until the tracking dye was 1 cm from the bottom. After electrophoresis, the gels were fixed and reacted overnight with ^{125}I-labeled rabbit antihuman vWF antibody as previously described. Identification of vWF multimers using ^{125}I-labeled affinity-purified anti-vWF IgG was performed as described.[3]

The platelet content of vWF antigen and ristocetin cofactor activity was measured in platelets that had been washed free of plasma constituents and then lysed by a previously published procedure.[14] For analyzing the multimeric structure of platelet vWF, equal parts of platelet-rich plasma and a buffer solution containing 13 mmol/L sodium citrate, 28 mmol/L glucose, 123 mmol/L sodium chloride, 5 mmol/L disodium EDTA, 6 mmol/L *N*-ethylmaleimide, and 0.1 mmol/L leupeptin (pH 6.5) were mixed and then spun at 1,000 g for 25 minutes at 4 °C. After a second centrifugation, the pellet was resuspended in no more than 2 mL of a buffer composed of 10 mmol/L Trizma base, 140 mmol/L sodium chloride, 5 mmol/L disodium EDTA, 6 mmol/L *N*-ethylmaleimide, and 0.1 mmol/L leupeptin (pH 7.4, adjusted with HCl). Washed platelets were counted, and the suspension was adjusted to give a count of approximately 2×10^9/mL and then frozen at −70 °C and thawed five times. After the final thawing, the suspension was centrifuged at 10,000 g for five minutes at 4 °C. The supernatant was diluted in electrophoresis sample buffer containing SDS[3] and analyzed for multimeric composition. In some experiments, washed platelets were lysed directly in the SDS-containing buffer.

DDAVP was infused intravenously into the propositus at a dose of 0.4 μg/kg of body weight. Blood bank cryoprecipitate was administered at the dose of 20 to 40 IU of factor VIIIC activity per kg of body weight. Blood samples were obtained, and the bleeding time was measured before, during, and after the infusion, according to a published protocol.[15,16]

RESULTS

The relevant clinical and laboratory findings in the propositus and her family are summarized in Table 1. In the patient, low plasma levels of Factor VIIIC, vWF antigen, and ristocetin cofactor activity, as well as the prolonged bleeding time, were consistent with the diagnosis of von Willebrand disease. The mother, sister, and brother had normal results.

Multimeric analysis of vWF using large-pore agarose gels (cast with 1.2% high-gelling temperature agarose) showed absence of the largest, slower-moving forms in the patient's plasma but a normal pattern in platelets (Fig 1). All multimers present in normal plasma were also present in the patient's mother and brother (Fig 1), as well as in the sister (not shown). After using short gels of higher resolving power (cast with 1.4% low-gelling temperature agarose), it became apparent that the previously reported[3] "triplet" structure characteristic of individual vWF multimers in normal plasma was not seen in the patient (Fig 2). On the contrary, the typical pattern of normal platelet vWF, distinct from that

Table 1. Relevant Anamnestic and Laboratory Findings in the Propositus and Her Family

Family Member	Bleeding History	Bleeding Time (min)	Factor VIIIC (U/dL)	vWF Antigen (U/dL)	Ristocetin Cofactor	RIPA
Propositus	Positive	>30	45	36	15	Decreased
Mother	Negative	6	180	200	160	Normal
Sister	Negative	5	160	126	100	Normal
Brother	Negative	6	85	73	66	Normal
Normal subjects

Range		2.31–6.01	57–150	49–145	51–140	

RIPA (ristocetin-induced platelet agglutination) was measured by adding varying amounts of ristocetin to platelet-rich plasma and determining the concentration (expressed in mg/mL) that induced aggregation with an initial velocity corresponding to 30% of maximum (see ref 10). The results of VIIIC, vWF antigen, and ristocetin cofactor activity are expressed in international units (IU) per deciliter, where 100 units is the amount present in 1 dL of pooled normal plasma. Results in normal subjects represent either arithmetic mean ± SD (bleeding time, RIPA) or geometric mean with 95% confidence limits (all other measurements).

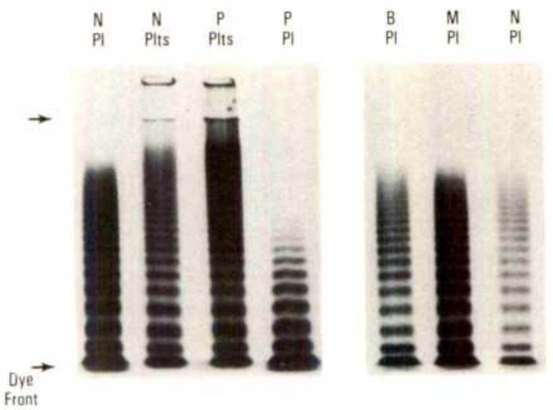

Fig 1. SDS gel electrophoresis in 1.2% high-gelling temperature agarose. The samples shown on the left are plasma (Pl) and platelets (Plts) from a normal individual (N) and the propositus (P); on the right, plasma from her mother (M) and brother (B). The arrow at the top indicates the interface between stacking and running gel; the one at the bottom indicates the dye front.

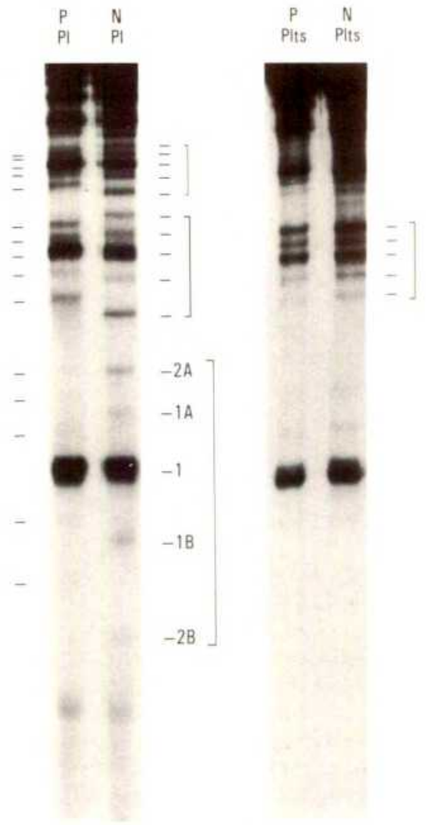

Fig 3. SDS agarose gel electrophoresis using a long gel of high resolving power. The samples shown are plasma (Pl) and platelets (Plts) from a normal individual (N) and the propositus (P). Marker bars denote the bands present in repeating multimers. The most intensely stained central band is indicated as 1; the two bands moving more slowly (above) are indicated as 1A and 2A; and the two moving faster (below) as 1B and 2B. The same bands can be detected in some multimers of increasing size but not in the larger multimers, which barely enter the running gel. Note the different mobility of satellite bands in the patient's plasma as compared with normal, but the similar mobility in normal and patient platelet vWF.

of plasma, was also seen in the patient's platelet vWF (Fig 2). The complex structure of individual multimers was further resolved by using longer agarose gels of high resolving power. In this system, the three to five smaller multimers appeared to consist of five bands, two migrating above and two below a most intense central band (Fig 3). The technique did not allow resolution of the complex structure of larger multimers, which barely entered this type of gel. In the plasma from more than 100 normal individuals, the mobility of satellite bands was consistently reproducible (data not shown; see also ref 4). When normal and patient plasma were compared side by side on the same gel, it became apparent that the central band of each vWF multimer had the same mobility in both cases, whereas the four satellite bands in the patient sample reproducibly migrated closer to the central band than did the normal counterparts (Fig 3). In this regard, the vWF structure in the patient's plasma was remarkably similar to that seen in platelet vWF. This finding was constantly observed on repeated analysis of two samples of the patient's plasma. On the contrary, the banding patterns of normal and patient platelet vWF were similar (Fig 3). The total protein content and vWF antigen levels were normal in the patient's platelets (0.1 IU of vWF antigen per milligram of platelet protein in the patient *v* 0.11 IU/mg in a normal control run at the same time; see also refs 14 and 16 for normal ranges). The ristocetin cofactor activity of the patient platelet vWF was also normal (0.12 IU/mg *v* 0.11 IU/mg). High-resolution gels demonstrated that the multimeric structure of plasma vWF in the patient's brother and mother was similar to normal (Fig 4). Therefore, the abnormality seen in the patient was not found in the other members of the family studied.

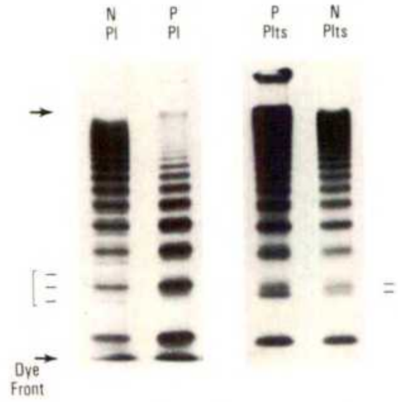

Fig 2. SDS gel electrophoresis in 1.4% low-gelling temperature agarose. The samples shown are plasma (Pl) and platelets (Plts) from a normal individual (N) and the propositus (P). The two arrows indicate, respectively, the interface between stacking and running gel (at the top) and the dye front (at the bottom). Marker bars denote the "triplet pattern" in normal plasma and the "doublet" in normal platelet samples.

The patient bled abnormally at surgery despite the administration of DDAVP, and satisfactory surgical hemostasis was achieved only after cryoprecipitate was given. No relevant shortening of the bleeding time was observed after

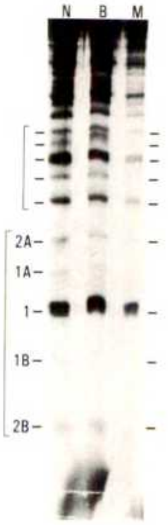

Fig 4. SDS agarose gel electrophoresis using a long gel of high resolving power. Plasma from the brother (B) and mother (M) of the propositus was analyzed along with a normal control plasma (N). The mobility of all bands appears to be similar in all cases. See Fig 3 for additional details on the interpretation of long gels.

DDAVP, even though vWF antigen and ristocetin cofactor activity were normalized (Table 2). Multimeric analysis of plasma vWF performed on short gels showed that the largest multimers appeared in the circulation immediately after the infusion of DDAVP and persisted for two to four hours (Fig 5). The complex structure of each multimer, however, remained abnormal. On long gels, additional bands previously not clearly detected became evident immediately after DDAVP infusion (Fig 6) and remained detectable for at least eight hours (not shown). Their mobility was similar to that of the satellite bands seen in normal plasma and contrasted with that of the abnormal bands still present in the post-DDAVP samples.

DISCUSSION

This patient, who had a lifelong bleeding tendency and a prolonged bleeding time, had low vWF antigen and ristocetin cofactor activity in plasma, contrasting with normal platelet levels of both moieties. In addition, there was a distinctive abnormality of plasma vWF multimeric structure, which

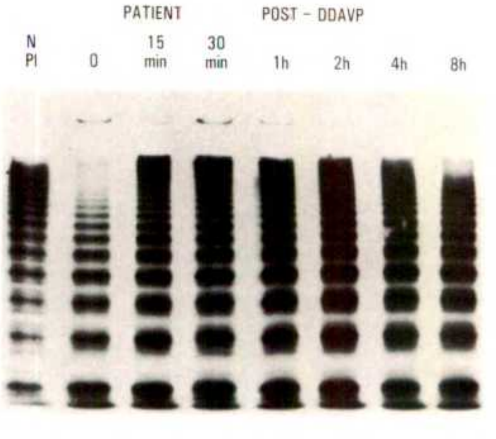

Fig 5. SDS agarose gel electrophoresis of samples obtained after DDAVP infusion. Normal plasma (NPl) is shown for comparison. Time measured in minutes (min) and hours (h) from the start of the administration (O) is reported. See Fig 2 for technical details.

became clearly evident using a combination of different agarose gels of varying resolving power.

Because of the absence of larger vWF multimers in plasma, this patient belongs to the category previously designated as Type II von Willebrand disease.[1] Five subtypes have been identified so far within this group (IIA, IIB, IIC, IID, and, recently, IIE), each of them characterized by distinct structural and functional abnormalities of vWF.[1,3,5-9,17] A discrepancy between the abnormal multimeric structure of vWF in plasma and the normal structure in platelets has been previously reported in two instances: Type IIB, as described by Ruggeri et al,[17] and Type IIA-3, reported by Weiss et al.[18] Type IIB patients are clearly different from this case because of the typical hyper-responsiveness of their platelet-rich plasma to low doses of ristocetin.[1,17] The opposite finding was observed in this patient, who had a decreased ristocetin-induced platelet agglutination. The cases called IIA-3 by Weiss et al also exhibited lack of larger vWF multimers in plasma, contrasting with a normal set of multimers in platelets. Because Weiss et al used low-resolution gels only and have not further characterized their variant, it cannot be established whether their patients are in some ways similar to the one described here.

The use of long agarose gels of high resolving power[4] has

Table 2. Relevant Laboratory Findings After DDAVP Infusion

Time	Factor VIIIC (U/dL)	vWF Antigen (U/dL)	Ristocetin Cofator (U/dL)	Bleeding Time (min)	Platelet Count ($\times 10^{-3}$/L)
0	45	36	15	>30	220
15′	87	40	47	—	182
30′	114	50	48	29	183
1 hr	107	56	55	—	198
2 hr	97	63	59	—	220
4 hr	85	73	68	>30	185
8 hr	59	72	44	—	196

DDAVP was infused at 0.4 μg/kg of body weight following the protocol described in ref 15. See Table 1 for normal values. Normal platelet count is 150 to 400 × 10^3/L.

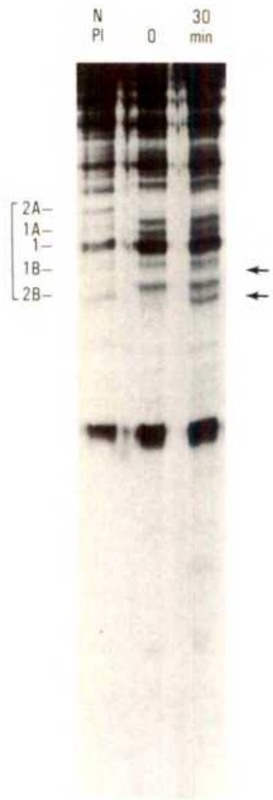

Fig 6. SDS agarose gel electrophoresis of samples obtained after DDAVP infusion. Refer to Fig 3 for details on the interpretation of long gels. Normal plasma (NPl) is shown for comparison. Plasma from the propositus was obtained before (O) and 30 minutes after DDAVP infusion. The marker bars denote the five bands present in the repeating vWF multimers. The two arrows on the right side indicate the post-DDAVP appearance in the patient's sample of two bands with mobility similar to normal bands 1B and 2B.

allowed a more precise definition of the complex banding pattern of individual vWF multimers in normal and patient's plasma and platelets. Five distinct bands could be resolved in each of the three to five smaller vWF multimers. The structure of the larger multimers could not be appreciated because they barely entered the small-pore long gels. Of the five bands, only the central, most intense one (sometimes resolved into a closely spaced doublet) showed similar mobility in both normal and patient's plasma vWF. The four satellite bands, on the contrary, had a distinctly altered mobility in the patient's plasma vWF as compared with normal. It is important to consider that the pattern seen in normal individuals was extremely reproducible, as demonstrated in well over 100 subjects. Therefore, the abnormal mobility of satellite bands seen in the plasma vWF of the patient reflects a unique, distinctive abnormality of this variant molecule. Also of interest is the fact that normal vWF of platelet origin exhibited a mobility of satellite bands different from that of the normal plasma counterparts but similar to that seen in the patient's plasma vWF. The patient's platelet vWF, in this regard, was identical to normal platelet vWF. At the present time, we cannot explain why plasma and platelet vWF show different mobility of the satellite bands seen in individual multimers, or why plasma vWF in the patient described here appears to have a structure similar to that seen in platelet vWF.

After infusion of DDAVP, additional satellite bands with a mobility similar to the satellite bands of normal plasma appeared transiently in patient's plasma, coexisting with the abnormal bands. Hence, vWF with an intact multimeric structure appears to be mobilized from storage sites by an appropriate stimulus such as DDAVP. At the present time, it remains unexplained why the multimeric structure of vWF becomes abnormal after release into the circulation. The abnormality could be detected despite addition to the plasma samples of a mixture of protease inhibitors that has been shown to partially prevent, in some cases, the absence of intermediate and larger vWF multimers in the plasma of patients with Type IIA von Willebrand disease.[19] At the present time, it is not possible to define the correlation, if any, between structural alteration of individual multimers and lack of the largest vWF multimers in plasma, despite their presence in platelets. In any case, our results demonstrate that the vWF molecule present in storage sites and mobilized by DDAVP was impaired in its function after release into the circulation. Larger vWF multimers, as well as satellite bands with a mobility identical to that of bands present in normal plasma, appeared in the patient's circulation and persisted for several hours after DDAVP infusion, but the bleeding time and the hemorrhagic tendency were not corrected, indicating that a dysfunctional protein was present.

The modality of genetic transmission of this newly described abnormality of vWF remains unclear. The mother and the two siblings of the propositus had a negative bleeding history and normal vWF. The father also had a negative bleeding history but had died before the patient came to our attention, and no data were available as to the structure of his vWF. The propositus had a lifelong bleeding tendency, so that the possibility of an acquired von Willebrand syndrome is remote. She had no descendants, however, to allow further insights into the mode of inheritance of this alteration. Altogether, the most likely possibility is that this new variant is transmitted as a phenotypically recessive trait.

In conclusion, these studies define a new variant form of von Willebrand disease, characterized by a distinctive aberration of vWF multimeric structure and impaired function of the molecule. In keeping with terminology that has been used previously, we propose that this variant be designated Type IIF von Willebrand disease.

Activation of Plasminogen by Tissue Plasminogen Activator on Normal and Thrombasthenic Platelets: Effects on Surface Proteins and Platelet Aggregation

By Raphael B. Stricker, Dan Wong, Donny Tak Shiu, Patrick T. Reyes, and Marc A. Shuman

Tissue plasminogen activator (TPA) converts plasminogen to plasmin within the fibrin clot, thus localizing activation of fibrinolysis. To determine the extent to which platelets promote activation of plasminogen by TPA, we studied the interaction of TPA and plasminogen with unstimulated platelets. Normal washed platelets incubated in the presence of physiologic concentrations of plasminogen (180 μg/mL) and TPA (20 ng/mL) failed to generate plasmin activity. In contrast, incubation of platelets with TPA concentrations achieved during thrombolytic therapy (40 to 800 ng/mL) produced a tenfold to 50-fold increase in plasmin activity. After exposure to plasminogen and 200 ng/mL of TPA for one hour, platelets failed to agglutinate in the presence of ristocetin. Incubation of platelets suspended in autologous plasma with 400 ng/mL of TPA for one hour also inhibited ristocetin-induced agglutination. Exposure of platelets to plasminogen and increasing concentrations of TPA correlated with a decrease in glycoprotein Ib (GPIb) and an increase in glycocalicin, as shown by immunoblotting. The glycoprotein IIb/IIIa (GPIIb/IIIa) complex and a 250,000-dalton protein also disappeared from washed platelets after incubation with plasminogen and 200 ng/mL of TPA for one hour. These platelets failed to aggregate in the presence of adenosine diphosphate (ADP) or gamma thrombin, although aggregation in response to calcium ionophore A23187 and arachidonic acid remained intact. However, aggregation in response to all four agonists was normal when platelets were incubated with TPA in the presence of autologous plasma. Platelets from a patient with Glanzmann's thrombasthenia also generated plasmin in the presence of TPA. Hydrolysis of GPIb and inhibition of ristocetin-induced agglutination occurred to a lesser extent with these platelets than with control platelets. We conclude that platelets provide a surface for activation of plasminogen by pharmacologic amounts of TPA. Plasmin generation leads to degradation of GPIb and decreased ristocetin-induced agglutination in normal and thrombasthenic platelets, as well as degradation of GPIIb/IIIa in normal washed platelets and inhibition of ADP and gamma thrombin-induced aggregation. These findings suggest that pharmacologic concentrations of TPA may cause platelet dysfunction due to plasmin generation on the platelet surface.

THROMBOLYSIS is a promising mode of treatment for acute myocardial infarction and thromboembolic disease.[1-5] Infusion of streptokinase, a nonspecific activator of fibrinolysis, is frequently associated with bleeding complications.[4,5] Tissue plasminogen activator (TPA) has recently been used in the treatment of acute myocardial infarction.[1] Activation of plasminogen by TPA requires fibrin. Thus, TPA provides a mechanism for specifically activating plasminogen at the site of thrombus formation. Localization of TPA to the fibrin clot is thought to reduce the risk of bleeding by preventing systemic activation of plasminogen and generalized fibrinolysis.[5]

Adelman et al[6] have reported that streptokinase interferes with ristocetin-induced platelet agglutination by means of plasmin-mediated degradation of platelet glycoprotein Ib (GPIb), the receptor for von Willebrand factor. Miles and Plow[7] recently showed that unstimulated platelets not only bind plasminogen, but also enhance its activation in the presence of a pharmacologic concentration of TPA, urokinase, or streptokinase. In the experiments described in this paper, we have examined the role of platelets in activation of plasminogen by TPA and the subsequent effect of plasmin on platelet membrane glycoproteins.

MATERIALS AND METHODS

Recombinant tissue-type plasminogen activator (500 μg/mL) was obtained from Genentech, Inc, Burlingame, Calif. Gamma thrombin (1.78 mg/mL), a generous gift of Dr John Fenton, New York State Department of Health, Albany, NY, was prepared as described.[8] Adenosine diphosphate ([ADP] Sigma Chemical Co, St Louis), arachidonic acid (Bio-Data, Willow Grove, Pa), calcium ionophore A23187 (Sigma), and ristocetin (Pacific Hemostasis, Bakersfield, Calif) were used for platelet aggregation studies. S-2251 was obtained from KABI via Helena Laboratories, Beaumont, Tex. Human Glu-plasminogen (1.25 mg/mL), kindly provided by Dr Craig Rice of Codon, Inc, South San Francisco, Calif, was prepared as previously described.[9] The plasminogen was stored in ε-aminocaproic acid (EACA) and dialyzed against Tyrode's buffer immediately before use to remove the EACA. Plasmin was purchased from Sigma and was used as a standard for activity, which was expressed in caseinolytic units (CU) per milliliter defined according to Squouris et al.[10] ^{14}C-Serotonin (5-hydroxytryptamine creatine sulfate-^{14}C) was obtained from Amersham Corp, Arlington Heights, Ill. Rabbit antibody against GPIb was the gift of Dr Joan Fox of the Gladstone Foundation Laboratories, San Francisco. Rabbit antibody against glycoproteins IIb and IIIa (GPIIb/IIIa)[11] was generously provided by Dr Rodger P. McEver of the University of Texas Health Science Center, San Antonio.

Control platelets and thrombasthenic platelets were prepared in the presence of prostaglandin E_1 (1 μg/mL) by isopycnic centrifugation over a Stractan gradient.[12] Thrombasthenic platelets were obtained from a patient with a bleeding time >30 minutes. These platelets failed to aggregate in the presence of ADP, collagen, or gamma thrombin, and they were shown to be more than 90% deficient in GPIIb/IIIa by immunoblotting with rabbit antibody raised against these glycoproteins.[11] The platelets were suspended in

Tyrode's buffer at 200,000/μL and incubated with plasminogen and TPA for one hour at 37 °C as shown in Table 1.

After incubation, the platelets were centrifuged and the supernatants removed for assay of plasmin activity using substrate S-2251.[13] A standard curve was constructed using substrate and known amounts of plasmin. Platelets from (F) in Table 1 were resuspended in Tyrode's buffer, and aggregation using ristocetin (1.5 mg/mL), ADP (4 μmol/L), calcium ionophore A23187 (13 μg/mL), arachidonic acid (500 μg/mL), or gamma thrombin (2 μg/mL) was performed using a Payton dual-channel aggregometer (Payton Scientific, Inc, Buffalo, NY). Platelets from (A) and (B) in Table 1 were used for control aggregometry. In the case of platelet-rich plasma (PRP), control platelets were suspended in autologous plasma at 200,000/μL and incubated with TPA for one hour at 37 °C. Aggregation was then performed using the same agonist concentrations. PRP incubated with TPA buffer alone was used as a control.

Labeling of control platelets with ^{14}C-serotonin was performed as previously described.[14] After labeling in PRP, the platelets were isolated over Stractan and incubated with TPA and plasminogen for one hour at 37 °C as described. The platelets were centrifuged, and ^{14}C-serotonin release was measured in the supernatants. Radiolabeled platelets incubated with plasminogen or TPA alone were used as controls. The results were expressed as the percentage of ^{14}C-serotonin release above the percentage of release from controls.

Immunoblotting was performed as previously described.[15] Platelet samples from A, B, and D through H (Table 1) were solubilized in 2% sodium dodecylsulfate (SDS) at 1 × 10^9/mL. Fifty-microliter aliquots were electrophoresed in SDS-5% polyacrylamide gels under nonreducing conditions. After transfer to nitrocellulose, the platelets were incubated with rabbit anti-GPIb,[15] which recognizes platelet GPIb as well as glycocalicin on immunoblots, or with rabbit anti-GPIIb/IIIa.[11] The anti-GPIb antibody was used at a dilution of 1:500, while the anti-GPIIb/IIIa antibody was diluted 1:2,000 for immunoblotting. Antibody binding was detected using a biotin-avidin peroxidase system.[15]

RESULTS

Figure 1 demonstrates plasmin activity generated when platelets are incubated with a physiologic concentration of plasminogen[16] and increasing concentrations of TPA. Incubation of platelets with either plasminogen or TPA alone generated no plasmin activity. Similarly, plasmin activity was not seen after incubation of plasminogen with TPA in the absence of platelets or in the presence of washed red blood cells. Incubation of platelets and plasminogen with a physiologic concentration of TPA (20 ng/mL)[2] failed to generate protease activity. However, incubation with concentrations of TPA achieved during treatment of patients[2] produced increasing amounts of plasmin activity from 0.20 to 0.55 CU/mL. Platelets from four controls generated similar plasmin levels, and the results were reproducible in four experiments. Incubation of thrombasthenic platelets with plasminogen and TPA produced similar levels of plasmin activity from 0.10 to 0.45 CU/mL on three occasions. Plasminogen concentrations of 18 μg/mL yielded the same results as concentrations of 180 μg/mL in the presence of TPA, indicating a significant substrate excess under physiologic conditions. Incubation of labeled platelets with plasminogen and the highest TPA concentrations (400 and 800 ng/mL) resulted in the release of 20% to 30% of ^{14}C-serotonin, indicating partial platelet activation at these concentrations of TPA and plasminogen.

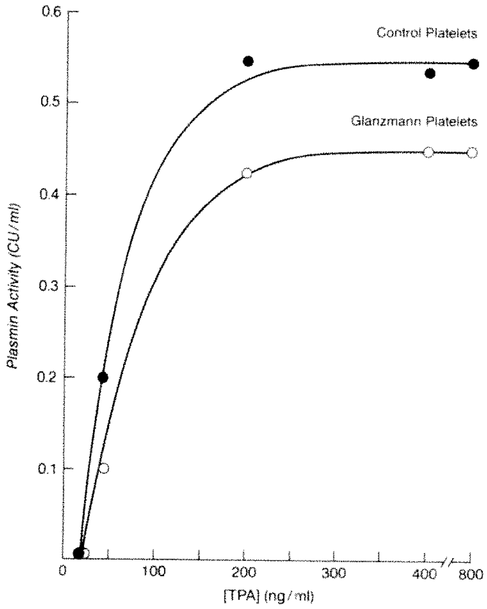

Fig 1. Plasminogen activation by TPA using control and thrombasthenic platelets. Washed platelets were incubated with plasminogen and increasing concentrations of TPA for one hour at 37 °C. The platelets were centrifuged and the supernatant was assayed for plasmin activity as described in Materials and Methods. Incubation of platelets with TPA alone, plasminogen alone, or plasminogen plus a physiologic TPA concentration (20 ng/mL) failed to generate plasmin activity. Platelet exposure to plasminogen and TPA concentrations of 40, 200, 400, and 800 ng/mL yielded plasmin activities of 0.20 to 0.55 CU/mL for control platelets and 0.10 to 0.45 CU/mL for thrombasthenic platelets.

Figure 2 shows the results of immunoblotting of platelet proteins after incubation of intact platelets with plasminogen and varying concentrations of TPA. In control platelets (Fig 2A), a major band of molecular weight (mol wt) 170,000 representing GPIb and a minor band of mol wt 250,000 are detected by the GPIb antibody. With increasing amounts of TPA, the 170,000- and 250,000-dalton bands decrease in intensity, and simultaneously, a 150,000-dalton band appears on the blots and then disappears at the highest TPA concentration. This suggests plasmin-induced degradation of

Table 1. Incubation Concentrations of Platelets, TPA, and Plasminogen

	A	B	C	D	E	F	G	H

TPA ng/mL	—	200	200	20	40	200	400	800
PLG μg/mL	180	—	180	180	180	180	180	180

PLG, plasminogen.

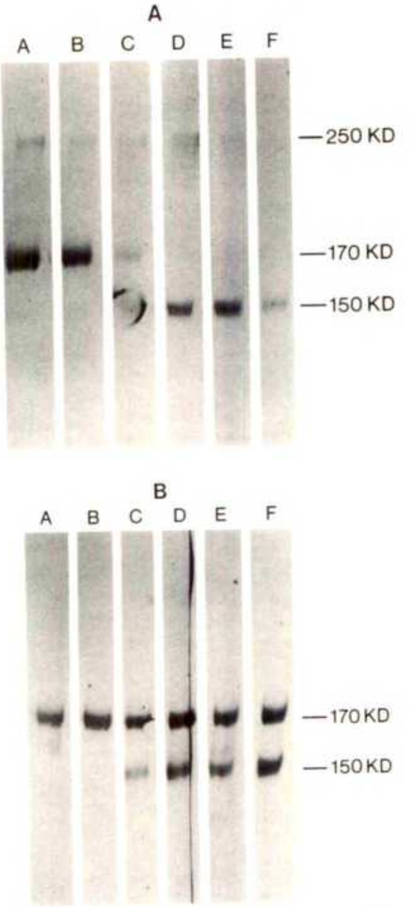

Fig 2. Effect of TPA and plasminogen on platelet GPIb. Washed platelets were incubated with plasminogen and increasing concentrations of TPA for one hour as described in Materials and Methods. The platelet proteins were subjected to SDS-PAGE, transferred to nitrocellulose, and incubated with rabbit anti-GPIb antibody followed by biotin-conjugated goat F(ab)'$_2$ anti-rabbit IgG and avidin peroxidase. Lane A, platelets incubated with TPA 400 ng/mL alone; lane B, platelets incubated with plasminogen and TPA 20 ng/mL; lane C, platelets incubated with plasminogen and TPA 40 ng/mL; lane D, platelets incubated with plasminogen and TPA 200 ng/mL; lane E, platelets incubated with plasminogen and TPA 400 ng/mL; lane F, platelets incubated with plasminogen and TPA 800 ng/mL. (A) Normal platelets. (B) Thrombasthenic platelets.

GPIb and a higher mol wt protein with consequent generation of the proteolytic cleavage product glycocalicin.[6] Glycocalicin is also formed when thrombasthenic platelets are exposed to TPA and plasminogen, but the GPIb band is incompletely degraded (Fig 2B). Less GPIb is cleaved in the thrombasthenic platelets exposed to a plasmin concentration of 0.45 CU/mL (Fig 2B, lanes D through F) than in normal platelets exposed to a plasmin concentration of 0.20 CU/mL (Fig 2A, lane C). Thus, thrombasthenic platelets appear to be more resistant to the effect of plasmin than do control platelets. In addition, the 250,000-dalton protein is not seen in the thrombasthenic platelets. Thus, these platelets appear to be deficient in a higher-mol-wt protein that is degraded by plasmin.

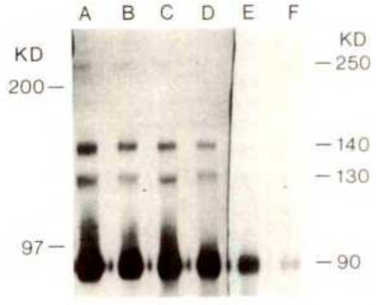

Fig 3. Effect of TPA and plasminogen on GPIIb/IIIa in normal platelets. The platelet preparation and conditions were as described in Fig 2. Lane A, platelets incubated with TPA 400 ng/mL alone; lane B, platelets incubated with plasminogen and TPA 20 ng/mL; lane C, platelets incubated with plasminogen and TPA 40 ng/mL; lane D, platelets incubated with plasminogen and TPA 200 ng/mL; lane E, platelets incubated with plasminogen and TPA 400 ng/mL; lane F, platelets incubated with plasminogen and TPA 800 ng/mL. Note bands at 250 kd, 140 kd, 130 kd, and 90 kd that disappear after exposure to TPA and plasminogen.

Figure 3 shows the results of immunoblotting using rabbit anti-GPIIb/IIIa. In control platelets exposed to TPA alone (lane A), four bands are detected by the GPIIb/IIIa antibody: the 250,000-dalton protein, two proteins of mol wt 140,000 and 130,000 corresponding to GPIIb,[11] and a 90,000-dalton protein corresponding to GPIIIa. After exposure of platelets to plasminogen and increasing concentrations of TPA, the four bands are no longer detectable (lane F). Thrombasthenic platelets do not contain these bands even without exposure to plasminogen and TPA (data not shown). Thus, exposure of platelets to TPA and plasminogen results in degradation of GPIIb/IIIa. In addition, the immunoblot findings with anti-GPIIb/IIIa antibody confirm the absence of the 250,000-dalton protein in thrombasthenic platelets, as suggested by the findings with anti-GPIb antibody.

Figure 4 shows the results of ristocetin-induced agglutination of washed platelets after exposure to plasminogen and 200 ng/mL of TPA for one hour. Ristocetin-induced platelet agglutination was inhibited by 80% compared with control platelets. In contrast, thrombasthenic platelets showed only a 30% inhibition of ristocetin-induced agglutination even after exposure to plasminogen and 400 ng/mL of TPA. However, the agglutination of untreated thrombasthenic platelets by ristocetin was 20% less than that of normal platelets in the washed platelet system. This difference is unexplained.

Figure 5 shows the effect of TPA on ristocetin-induced agglutination of normal platelets suspended in autologous plasma. Although 200 ng/mL of TPA had no effect on platelet agglutination, incubation of PRP with 400 ng/mL of TPA completely inhibited ristocetin-induced agglutination. These TPA concentrations generated plasmin activities of 0.04 and 0.20 CU/mL, respectively, in PRP. Thus, TPA exerts its effect both in a washed platelet system and in PRP, although in PRP, a higher concentration of TPA is needed to achieve the same effect as with washed platelets.

Figure 6 shows the aggregation curves of normal washed platelets in response to ADP, gamma thrombin, arachidonic acid, or calcium ionophore A23187. Exposure of platelets to

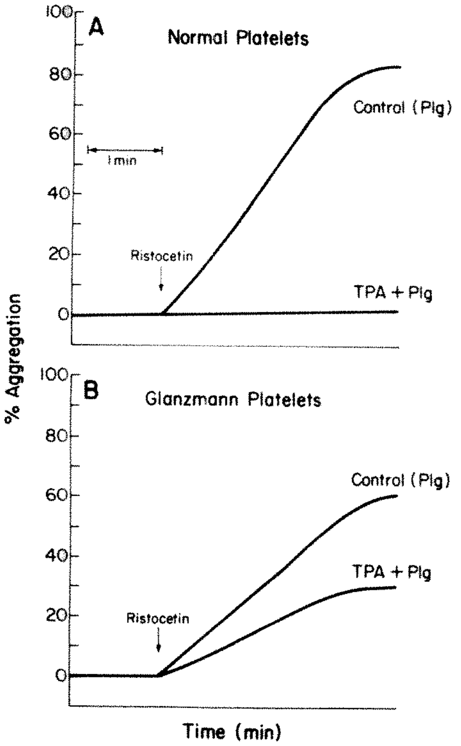

Fig 4. Ristocetin-induced agglutination of washed normal and thrombasthenic platelets after exposure to TPA. Washed platelets were incubated with plasminogen alone (control) or with plasminogen plus TPA 200 ng/mL (TPA + PLG) for one hour at 37 °C. After the platelets were washed, aggregometry was performed with ristocetin 1.5 mg/mL. Panel A, ristocetin-induced agglutination of normal platelets. Panel B, ristocetin-induced agglutination of thrombasthenic platelets.

plasminogen and 200 ng/mL of TPA for one hour at 37 °C inhibited the aggregation response to ADP and gamma thrombin by 80%. In contrast, platelet aggregation in response to arachidonic acid and calcium ionophore remained intact after TPA exposure. However, when PRP was substituted for washed platelets, aggregation in response to all four agonists remained intact, even after platelet exposure to 800 ng/mL of TPA (data not shown).

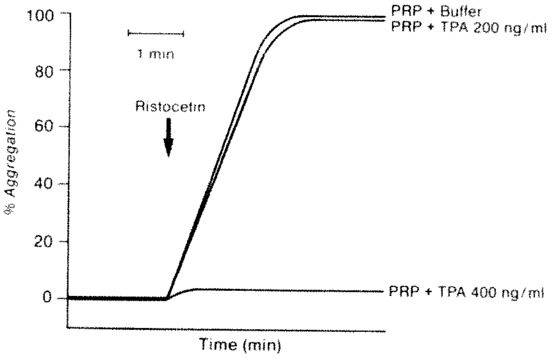

Fig 5. Ristocetin-induced agglutination of PRP. Platelets were suspended in autologous plasma at 200,000/μL and incubated with TPA 200 or 400 ng/mL for one hour at 37 °C. Ristocetin 1.5 mg/mL was then added, and aggregometry was performed. PRP incubated with TPA buffer alone was used as a control.

Washed platelets were incubated with TPA alone (control) or with plasminogen plus TPA 200 ng/mL for one hour at 37 °C. Panel A, control aggregation curves. Panel B, platelet aggregation after exposure to plasminogen and TPA.

DISCUSSION

In this study, we have shown that washed platelets incubated in the presence of plasminogen and pharmacologic concentrations of TPA produced a tenfold to 50-fold increase in plasmin activity. Exposure of platelets to TPA and plasminogen resulted in a decrease in GPIb and an increase in glycocalicin, as shown by immunoblotting. The platelets failed to agglutinate in the presence of ristocetin after exposure to pharmacologic concentrations of TPA. In addition, GPIIb/IIIa was no longer immunologically detectable in these platelets, and the aggregation response to ADP and gamma thrombin was inhibited. Thrombasthenic platelets generated slightly reduced amounts of plasmin in the presence of TPA, and ristocetin-induced agglutination was not inhibited to the same extent as in normal platelets. By immunoblotting, the thrombasthenic platelets also appeared to be less susceptible to degradation of GPIb.

Our findings have three significant implications. First, we have shown that unstimulated platelets incubated with a physiologic concentration of TPA do not generate plasmin. Therefore, under physiologic conditions, platelets do not provide a mechanism for plasminogen activation by TPA. Second, it appears that unstimulated platelets can interact with pharmacologic doses of TPA with consequent plasmin generation. Third, the amount of plasmin generated by low therapeutic levels of TPA is capable of degrading GPIb, the von Willebrand factor binding site on platelets, thereby inhibiting platelet adhesion. GPIIb/IIIa also appears to be degraded by plasmin, although this does not occur in PRP.

Thus, TPA has the potential to cause platelet dysfunction at concentrations well within the therapeutic range[2] by means of plasmin generation and degradation of GPIb.

Our study suggests that platelet-dependent activation of plasminogen by TPA does not require GPIIb/IIIa. However, thrombasthenic platelets appear to be less susceptible to the action of plasmin on GPIb, since there was less inhibition of ristocetin-induced agglutination and less degradation of GPIb in these platelets at a moderate plasmin concentration (0.45 CU/mL). These findings imply that GPIIb/IIIa may be involved in the interaction of plasmin with platelets. Alternatively, thrombasthenic platelets may contain more GPIb than do control platelets, so that cleavage of this membrane glycoprotein by plasmin is incomplete. The residual GPIb would therefore be sufficient to allow platelet agglutination by ristocetin even in the presence of moderate levels of plasmin activity.

An additional finding in normal platelets is that a mol wt = 250,000 protein disappears in the presence of plasmin. In contrast, the 250,000-dalton band is not seen in thrombasthenic platelets even before exposure to plasmin. Furthermore, the 250,000-dalton protein was not detected by immunoblotting in platelets from four other thrombasthenic patients (data not shown). The nature of this protein and its role in platelet function are unknown. It represents either an additional protein that is decreased or missing in thrombasthenic platelets or a dimer of GP IIb-IIIa.

Previous studies using rabbit platelets[17] or human platelets[18] have shown that plasmin levels of 0.9 CU/mL or more can directly cause platelet activation and aggregation. Our results demonstrate that TPA does not generate enough plasmin to cause direct platelet aggregation, in accord with the observation of Schafer and Adelman[19] that plasmin concentrations of 0.5 CU/mL do not aggregate washed human platelets. However, at this plasmin concentration, partial platelet activation does seem to occur, as evidenced by ^{14}C-serotonin release. Our findings differ from those of Deguchi et al,[20] who described the interaction of a platelet extract with *Lys*-plasminogen in the presence of trace amounts of TPA. In contrast, our study used intact platelets with physiologic amounts of Glu-plasminogen and pharmacologic concentrations of TPA. Thus, plasmin generation in moderate quantities appears to occur on the platelet surface in the presence of TPA.

A major question concerns the applicability of our findings to in vivo platelet function in the presence of TPA. We know of no previous study in which platelet function was examined during TPA administration. Adelman et al[6] showed that when platelets are incubated with streptokinase at concentrations producing as little as 0.05 CU/mL of plasmin, ristocetin-induced platelet agglutination is inhibited. Little data exists on in vivo correlates of plasmin activity, however.[19] Our results using PRP suggest that plasmin generated by TPA levels achieved during thrombolytic therapy may interfere with platelet adhesion despite the presence of circulating plasmin inhibitors. However, we could show no effect on platelet aggregation in response to ADP, gamma thrombin, arachidonic acid, or calcium ionophore when PRP was substituted for washed platelets. Further studies in patients receiving TPA therapy are necessary to determine whether TPA interferes with platelet function by means of plasmin generation in vivo as well as in vitro.

In summary, we have shown that TPA interaction with plasminogen and washed platelets leads to plasmin generation, inhibition of platelet aggregation, and degradation of glycoproteins Ib and IIb/IIIa. Plasmin is generated on control and thrombasthenic platelets, but the effect of plasmin on thrombasthenic platelets appears to be decreased. The mechanism of TPA interaction with platelets and the risk of bleeding due to this interaction remain to be determined.

ACKNOWLEDGMENT

We thank Dr Joan Fox of the Gladstone Foundation Laboratories, San Francisco, for providing the anti-GPIb antibody, and Dr Rodger P. McEver of the University of Texas Health Science Center, San Antonio, for providing the anti-GPIIb/IIIa antibody. We also thank Dr Marion Koerper for providing thrombasthenic platelets from two of the patients, and Paul Lysenko, Fay Weimer, and Debra Singer for technical assistance.

Human T Lymphotropic Virus Type III Infection of Human Alveolar Macrophages

By Syed Z. Salahuddin, Richard M. Rose, Jerome E. Groopman, Phillip D. Markham, and Robert C. Gallo

The human T-cell lymphotropic virus type III (HTLV-III) is the etiologic agent of the acquired immunodeficiency syndrome (AIDS) and preferentially infects T4 lymphocytes. Other cell types, notably B lymphocytes and other nonlymphoid cells, also have been reported to be infected in vitro by HTLV-III. We now report on the susceptibility of human pulmonary macrophages to infection with HTLV-III in vitro. Alveolar macrophages infected with HTLV-III produced low levels of virus that could be transferred to allogeneic human peripheral blood mononuclear leukocytes as long as 2 weeks after initiation of infection. Unlike HTLV-III infection of T lymphocytes, macrophages appeared more resistant to viral-mediated cytopathic effects. Primary cultures of pulmonary macrophages from two of four patients with AIDS spontaneously produced low levels of virus detected as precipitable reverse transcriptase activity, suggesting that these cells were infected in vivo. Because tissue macrophages are long-lived cells, they may act as a reservoir of HTLV-III, capable of transmitting the virus to other susceptible cells such as T lymphocytes, causing periodic low-level viremia. Macrophage infection with HTLV-III may be one mechanism for the establishment of viral persistence in infected hosts.

© 1986 by Grune & Stratton, Inc.

THE human T lymphotropic virus type III (HTLV-III) has been demonstrated to be the primary causative agent of acquired immunodeficiency syndrome (AIDS) and related disorders.[1-4] HTLV-III has been recovered from several body tissues and fluids, including peripheral blood lymphocytes, cell-free plasma, lymphocytes in saliva, cerebrospinal fluid (CSF), tears, and semen.[4-5] Preliminary studies suggest that the receptor for HTLV-III infection is related to or closely associated with the surface antigen T4 found on helper/suppressor T cells.[6-8] In vitro, B lymphoblastoid cell lines, and Epstein-Barr virus (EBV)-transformed fresh lymphocyte have been infected with HTLV-III,[9,10] and a recent report suggested the possible infection of human macrophages.[11] Pathologic studies of simian brains of animals infected with simian T lymphotropic virus type III (STLV-III), a retrovirus related to HTLV-III, show by electron microscopy viral particles in macrophages.[12] Furthermore, nonlymphoid cells in the brain, possibly glial cells, are infected with HTLV-III in some patients with AIDS and dementia.[13] These studies suggest that a number of cells other than T cells may be infected with HTLV-III. We now report on the infection of human alveolar macrophages in vitro and provide suggestive data that these cells may be infected in vivo as well.

MATERIALS AND METHODS

Pulmonary macrophages were harvested from healthy volunteers and from patients with AIDS by broncholavage using previously described methods.[14] Informed consent was obtained from all participants and the procedures were approved by the Institutional Review Board of the New England Deaconess Hospital. The adherent cell population was obtained from the lung by incubation on plastic and multiple washes with phosphate-buffered saline (PBS) were performed to dislodge any nonadherent cells. The resulting adherent population was studied morphologically with inverted and phase contrast microscopy and tested for phagocytic capacity for 1.1-μm latex beads.[15,16] The adherent cells were tested for nonspecific esterase (naphthol acetate esterase).[17] Pulmonary macrophages were also assayed for the expression of cell surface antigens OKT1, OKT3, OKT4, OKT8, and OKT11 (Ortho Pharmaceuticals, Raritan, NJ); Leu 1, Leu 3a, Leu4, and Leu 12 (Becton Dickinson, Mountain View, Calif); and B1 and B4 (Coulter Immunology, Fla) as previously described.[18] To minimize the possible nonspecific staining due to the use of murine monoclonal antibodies, antimouse immunoglobulin conjugate was included in immunoassays. Adherent cells from healthy volunteers as well as AIDS patients were infected at days 3 through 5 after plating. These cells were incubated at 37 °C in RPMI 1640 medium after diethylaminoethanol (DEAE) treatment for 20 minutes and then cultured with standard titrated infectious alliquots of HTLV-III harvested from H9 cells.[3] Controls consisted of DEAE-treated macrophages exposed to the supernatants obtained from uninfected H9 cells. Productive infection with HTLV-III was measured by quantitation of reverse transcriptase activity in supernatant fluid[2-5] under the assay conditions used; a cell culture was judged positive when the cpm using $dT_{15} \cdot rA_n$ primer template was $\geq 5{,}000$ and was greater than or equal to threefold higher than cpm using $dT_{15} \cdot dA_n$ as primer template. Staining of target pulmonary macrophages with monoclonal antibodies to the HTLV-III correlated with p24 and p15 antigens to determine the percentages of positive cells.[2-5] Electronmicroscopy and transmission of HTLV-III from supernatant fluids of human alveolar macrophage cultures to normal peripheral blood lymphocytes was performed as previously described.[2-5]

Characterization of Adherent Cells

Morphology. Standard differential counts were performed on Wright's-Giemsa–stained cytocentrifuge-prepared cells to determine the gross morphology of the cell population and their state of differentiation. Myeloid cells through the metamyelocyte stage were classified as immature.

Cytochemistry. Published procedures were followed for the cytochemical evaluation of fresh and cultured cells. The tests performed included stains for naphthyl ASD chloracetate esterase,[14] α-naphthyl acetate esterase,[14] acid phosphatase,[15] and myeloperoxidase.[16]

Nitroblue tetrazolium reduction. The nitroblue tetrazolium (NBT) reduction test was performed on suspension and adherent

cells with or without the addition of freshly diluted tetradecamylphorbal acetate (TPA), as previously described.[13,17] Cells were incubated for 25 minutes at 37 °C in media containing 0.2% NBT and the desired concentration of TPA. Cells were rinsed twice with media, pelleted on microscope slides using Shandon-Elliot cytospin, and stained with Wright's-Giemsa. Cells with dark formazan deposits were scored positive.

Phagocytosis. Suspension cells were mixed with either sterile carbonyl iron (Technicon Instruments Corp, Tarrytown, NY) at a concentration of 10% (vol/vol) or with formalin-fixed *Candida albicans* at a concentration of 4 × 10^6/mL with or without the addition of freshly diluted TPA, and incubated at 37 °C for 25 minutes. After incubation, cells were rinsed twice with media, and cytocentrifuge smears were prepared; these were stained with Wright's-Giemsa before evaluation. Adherent cells on the plastic surface of culture flasks were treated with either carbonyl iron or *C albicans*, rinsed, and evaluated directly under an inverted microscope after Wright's-Giemsa staining.

Detection of EBV antigens and antibodies. Serum from donors were tested for the presence of antibodies reactive against Epstein-Barr virus nuclear antigen (EBNA) and EBV-virus capsid antigen (VCA), and cells were tested directly for these antigens by published procedures.[19]

Rosette formation. Leukocytes were tested for their ability to form rosettes with either sheep or bovine erythrocytes either directly (E rosette) after treatment of erythrocytes with anti-sheep or bovine erythrocyte serum (EA rosettes) or addition of C_5-deficient mouse complement to the EA preparation (EAC rosettes) by published procedures.[20]

Surface-bound immunoglobulin. The presence of cell surface-bound Ig (SIg) was determined by direct procedures using fluorescence-labeled $F(ab')_2$ fragments of anti-human IgG, A, and M.

Monoclonal antibody profile. Murine monoclonal antisera reactive with peripheral blood monocytes[22] was used to detect monocyte-macrophages. Reacting cells were identified using FITC-labeled anti-murine IgG, $F(ab')_2$-specific serum.

RESULTS

The adherent cell cultures obtained by broncholavage were tested following three to five days in cell cultures. At this time they were >98% monocytic, (>94% phagocytic for latex beads, and >99% positive for nonspecific esterase, indicating a nearly uniform population of alveolar macrophages). Furthermore, these cells were negative for T and B cell-related antigens OKT1, OKT3, OKT8, and OKT11; Leu 1, Leu 3a, Leu 4, and Leu 12; and B1 and B4. A low percentage of these adherent cells (2% to 3%) expressed the T4 antigen. This did not appear to be the result of low-level contamination of macrophage cultures with lymphocytes since these studies were performed on rigorously prepared and characterized adherent cells after 3 to 5 days in culture. One hundred percent of these adherent cells were positive for OKM1, M5 (Ortho Diagnostic), Leu M1, and M3 (Beckton Dickinson), and MO1 and MO3 (Coulter Immunology) monoclonal antibodies directed against monocytoid/macrophage cells. This further indicates lack of contamination of the cultures with lymphocytes.

The results of infecting pulmonary macrophages from normal donors and AIDS patients in vitro are shown in Table 1 and Fig 1. Primary macrophage cultures from AIDS patients demonstrated low levels of reverse transcriptase activity (threefold to fivefold background) observed in two of four cases, suggesting the presence of cellular infection in vivo. Despite this suggestion of viral infection, HTLV-III (or other viruses) could not be visualized by electronmicroscopy, and attempts to transmit HTLV-III from these cells to normal T cells were unsuccessful.

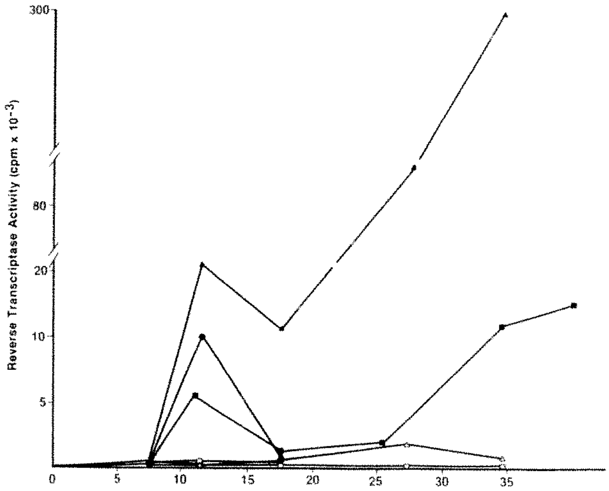

Fig 1. **Human alveloar macrophages obtained by broncholavage from normal volunteers were placed in tissue culture in RPMI 1640, and the adherent macrophages were infected with HTLV-III. Several of these specimens were tested as shown here for release of reverse transcriptase activity (RT). These cells were infected on day 5 and tested for RT at various time intervals for virus release. On day 22, fresh mononuclear peripheral blood leukocytes were added to these infected macrophages with a consequent rise in virus release. Uninfected cells from donor 5 □—□; cells infected with HTLV-III from donor 5 ■—■; uninfected cells from donor 6 △—△; cells infected with HTLV-III from donor 6 ▲—▲; uninfected cells from donor 7 ○—○; cells infected with HTLV-III from donor 7 ●—●.**

Pumonary macrophages from both AIDS patients and normal donors were susceptible to HTLV-III infection in vitro. As shown in Fig 1, 3 to 5 days after introduction to cell culture, adherent pulmonary macrophages from normal donors were exposed to HTLV-III, and levels of reverse transcriptase activity were detectable within 7 days. This production of virus was then amplified by addition to the culture of lectin-stimulated peripheral blood mononuclear cells from allogeneic donors on day 22 of culture. A marked increase in HTLV-III production was then obtained as detected by both release of precipitable reverse transcriptase activity and increase in the percentage of suspension cells expressing HTLV-III core-related proteins p15 and p24 (Table 1). The adherent cell population did not demonstrate gross cytopathic changes morphologically postinfection and was viable by trypan-blue exclusion for >65 days. Following HTLV-III infection of the adherent macrophage population, ~18% to 30% of the cells expressed HTLV-III core-related antigens, a much higher proportion of the macrophages than the T4 antigen-expressing population (2% to 4%).

DISCUSSION

These studies demonstrate that human pulmonary macrophages obtained from both normal volunteers and patients with AIDS are permissive for infection with HTLV-III.

Table 1. Infection of Alveolar Macrophages From Normal Donors and AIDS Patients HTLV-III, on Day 12 Postinfection

		Uninfected Cells		HTLV-III Infected Cells		
					IFA (% Positive)	
Specimen[*] Source	Patient No.	RT[†] Activity (cpm × 10^{-3})	IFA[‡] OKT4 (% Positive)	RT Activity (cpm × 10^{-3})	p15	p24
AIDS	1	3	<2	6	ND	ND
	2	–	ND	+	13	21
	3	±	<4	+	18	19
	4	–	ND	+	ND	ND
Healthy heterosexual donors	5	–	<4	6	30	29
	6	–	<3	11	25	18
	7	–	<4	23	19	24
	8	–	<4	5	29	32

ND, not done.

[*] Adherent cell cultures were established as described. These cells were >97% positive for nonspecific esterase (naphthyl acetate esterase) and ability to phagocytize latex beads; they were negative for T cell (eg, OKT1, or T3, OKT4, OKT8, Leu 1, Leu 3, and Leu 4 and for B cell (Leu 12, B1, and B4) antigens.

[†] Reverse transcriptase activity released into supernatant fluids of cell culture was determined as previously described: + positive, – negative, ± low levels of activity. These determinations were made every 5 days.

[‡] HTLV-III specific protein (p15, p24), T cell, and B cell markers were determined by immunofluorescence assays (IFA) as described.

Therefore, like retroviruses of other mammalian species, particularly visna and STLV-III, HTLV-III is capable of productively infecting mononuclear phagocytes. This infection appears to differ from that of lymphocytic cells in that the viability of the infected macrophages in vitro does not appear to be as adversely affected by HTLV-III. It is reasonable to speculate that mononuclear phagocytes may be infected in vivo in patients with HTLV-III–related diseases (HRD). The data of Shaw and colleagues demonstrating HTLV-III proviral DNA in nonlymphoid cells in brain tissues obtained from patients with AIDS-related dementia further support the concept that there are nonlymphoid targets of this retrovirus.[13] Because macrophages are relatively long-lived cells capable of close interaction with lymphocytes, and do not appear in vitro to be as susceptible to HTLV-III–induced cytopathic effects as do lymphocytes, it is possible that infected macrophages in vivo could propagate viral infection in the hosts by transfer of virus to lymphocytes. HTLV-III infection of mononuclear phagocytes could thereby be one mechanism for the establishment of viral persistence.

It is still undetermined whether in vitro HTLV-III enters the macrophages by specific interaction with a cell surface receptor, possibly related or unrelated to the T4 antigen, or whether the virus is simply phagocytosed and maintained in a viable state within vacuoles without integration as proviral DNA. Studies are underway to address these questions.

Because macrophages play an important role in the defense against certain neoplastic and infectious processes, alterations in these activities could contribute to host immunosuppression and further predispose to the development of malignancy and opportunistic infections. This is particularly clinically evident with respect to pulmonary macrophages in that patients with AIDS often manifest opportunistic infections of the lung. In this regard, it has been demonstrated that certain monocyte-macrophage functions such as antigen presentation are deficient in cells obtained from individuals with AIDS and related disorders.[19]

Strategies for anti-HTLV-III viral therapy, as well as immunomodulatory therapy, in patients with AIDS requires full definition of the target cells of this virus and possible reservoirs in vivo of viral infection. Our observations that in vitro pulmonary macrophage can be infected with HTLV-III and appear to be less susceptible to the cytopathic effects of this retrovirus suggest that tissue macrophages should be considered as potential reservoirs of HTLV-III in vivo.

Cytochemical, Immunologic, Chromosomal, and Molecular Genetic Analysis of a Novel Cell Line Derived From Hodgkin's Disease

By Hiroshi Kamesaki, Shiroh Fukuhara, Eiji Tatsumi, Haruto Uchino, Hirohiko Yamabe, Hiroshi Miwa,
Shigeru Shirakawa, Masakazu Hatanaka, and Tasuku Honjo

A novel cell line, KM-H2, was established from the pleural effusion of a patient with Hodgkin's disease of mixed cellular type. Multiple phenotypic studies were carried out with this cell line. Acid phosphatase and nonspecific esterase activities were detected. Rosette formation with T lymphocytes and the receptors for C3b and Fc portion of IgG were positive. Among the antigens tested with a total of 22 monoclonal antibodies defining hematopoietic cell subsets or lineages, Ki-1, Leu-M1, MCS1, HLA-DR, and OKT9 antigens were found to be positive. The other antigens reportedly specific for T cells, B cells, natural killer (NK) cells, monocytes, interdigitating reticulum (IR) cells and dendritic reticulum cells were negative. These phenotypic features were identical to those of the Sternberg-Reed (SR) and Hodgkin (H) cells in the fresh materials reported by other researchers. Moreover, the KM-H2 cells and the parental pleural effusion cells shared several structural chromosome anomalies. These findings indicated that the KM-H2 cells are derived from the SR and H cells. Molecular genetic analysis of the KM-H2 cells disclosed that the human immunoglobulin J_H gene was rearranged but not the JK gene, and that the human T cell receptor β chain gene was of the germline type. Based on these properties of the KM-H2 cells, Hodgkin's disease may be derived from a cell lineage other than T cell or B cell.

© 1986 by Grune & Stratton, Inc.

ALTHOUGH the Sternberg-Reed (SR) and Hodgkin (H) cells are regarded as the tumor cells in Hodgkin's disease, their nature and origin remain unclear. To clarify this question, a number of ultrastructural, histochemical, and immunologic studies have been performed on histological sections or after separation from biopsy materials. As a result, several cell lineages of the hematopoietic system have been suggested as candidates for the origin of the SR and H cells: T lymphocytes,[1] B lymphocytes,[2,3] macrophages,[4,5] granulocytes,[6] and dendritic reticulum cells,[7] as well as interdigitating reticulum (IR) cells.[8]

Faced with the difficulties of characterizing the SR and H cells, many investigators have attempted to establish in vitro cell lines derived from the SR and H cells. However, this has been hampered because these cells usually constitute only a minor population and seem to grow poorly in the hitherto available culture systems. Several permanent cell lines have been reported, but most of these do not appear to have arisen from typical SR and H cells, with the exception of the L428 cell line.[9]

We report here a novel cell line, KM-H2, established from the pleural effusion of a patient who was initially diagnosed as having Hodgkin's disease of mixed cellular type. We also describe its cytochemical, immunologic, and molecular genetic properties, and discuss the cellular origin of Hodgkin's disease.

MATERIALS AND METHODS

Establishment of the Cell Line

A 32-year-old man was admitted to our hospital in October 1969 with an enlarged left cervical lymph node. After biopsy of the lymph node, Hodgkin's disease of the mixed cellular subtype was diagnosed (Fig 1A and B), and confirmed by two independent pathologists. After extensive examination, the case was identified as clinical stage IV and was successfully treated with combination chemotherapy consisting of prednisone, vinblastine, and cyclophosphamide. Five years later, an abdominal mass, ascites, and bilateral pleural effusion appeared. Cytological examination of the pleural effusion revealed that they were almost all atypical cells, including a number of Hodgkinoid cells (Fig 2A). The patient died 5 days after thoracentesis. At autopsy, mediastinal, paraaortic, and mesenteric lymph nodes were enlarged. Multiple nodules were observed in the lungs, liver, spleen, kidneys, pleura, and peritoneum. Microscopic examination of lymph nodes and nodules showed Hodgkin's disease, lymphocyte depletion subtype (Fig 1C). The cells obtained by the thoracentesis were cultured at a concentration of 1×10^6 cells/mL in RPMI-1640 supplemented with 10% fetal calf serum (FCS), and 40% cell-free supernatant was obtained from the autologous pleural fluid. After 3 days, obvious cell growth was noted, with large floating clusters of cells. The cells were cultured in this condition for 2 weeks. Since then, they have been propagated in continuous culture for >5 years in RPMI 1640 with 10% FCS with a cell-doubling time of ~ 60 hours. The cell line was designated as KM-H2.

Detection of Epstein-Barr Virus

An indirect immunofluorescence test[10] was used for the detection of Epstein-Barr virus-associated nuclear antigen (EBNA).

Chromosome Preparations

Chromosome analysis was performed on KM-H2 cells and the parental pleural effusion cells. Metaphase preparations were obtained after the incubation of 0.05 μg/mL of colcemid, and fixed with methanol acetic acid (3:1). Chromosomes were banded by the trypsin-Giemsa and the Quinacrine staining methods.

Cytochemical Methods

In addition to routine staining with May-Grünwald-Giemsa, the following cytochemical tests were performed on cytocentrifuge preparations: Peroxidase, acid phosphatase,[11] alkaline phosphatase,[12] α-naphthyl acetate esterase,[13] and naphthol AS-D chloroacetate esterase.[13]

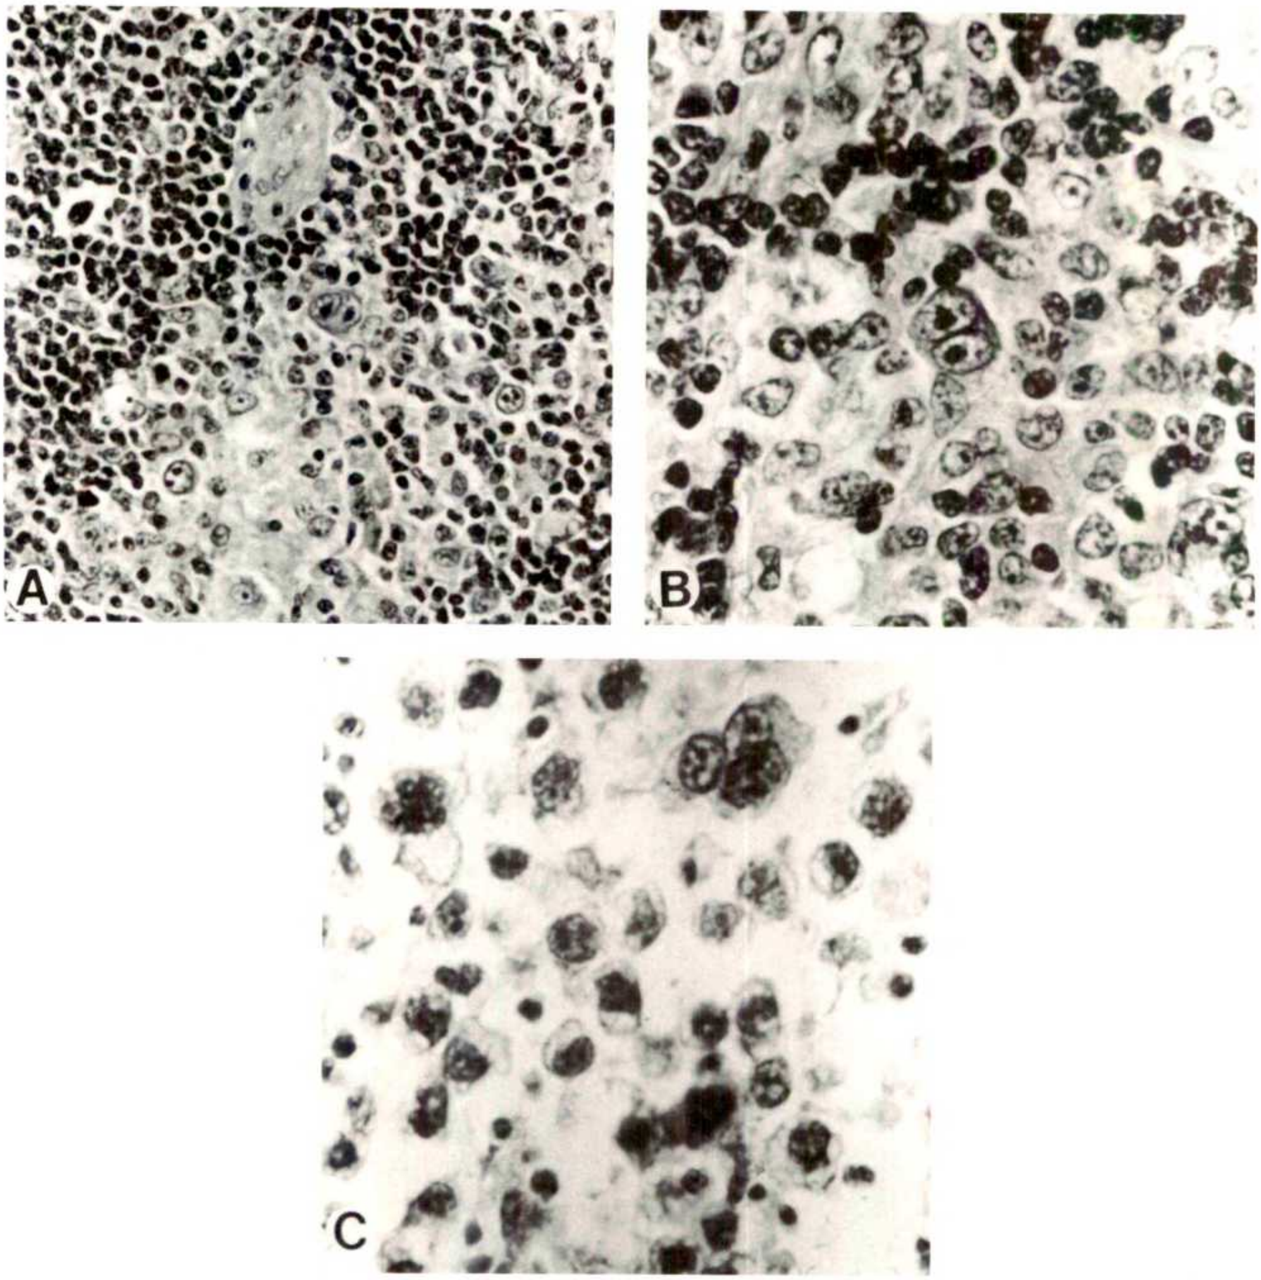

Fig 1. (A) Mixed cell population lying between the interlacing fibroblasts. A classical Sternberg-Reed cell is apparent (H&E ×100). (B) Higher magnification of a typical Sternberg-Reed cell (H&E ×400). (C) Histological appearance at autopsy (H&E ×500).

Studies for Immunologic Markers

Immunoperoxidase methods. Paraffin sections were deparaffinized with xylene and graded alcohol and rehydrated with phosphate-buffered saline (PBS; pH 7.6), as in routine processing. Cytocentrifuged smears were fixed in acetone, at 4 °C, for 10 minutes prior to immunostaining.

The staining procedures using anti-Leu M1 or heteroantisera against lysozyme, α1-antitrypsin, and S100 protein have been described elsewhere[14-16] in detail. The staining procedures with biotin-labeled peanut agglutinin were also performed as previously reported.[17]

Immunofluorescence tests. Cell surface immunoglobulin (Ig) and cytoplasmic Ig were tested by direct immunofluorescence. Antigens defined by mouse monoclonal antibodies were detected by indirect immunofluorescence. Terminal deoxynucleotidyl transferase (TdT) was also stained by indirect immunofluorescence as previously described.[18] The heteroantisera and monoclonal antibodies used in this study are summarized in Table 1. Immunofluorescence was judged under an Olympus fluorescence microscope.

Rosette assays. Cells bearing receptors for sheep erythrocytes,[38] Fc portion of IgG and IgM,[39] and complement[40] were detected as reported previously. The T cell rosette assay was also performed as previously described.

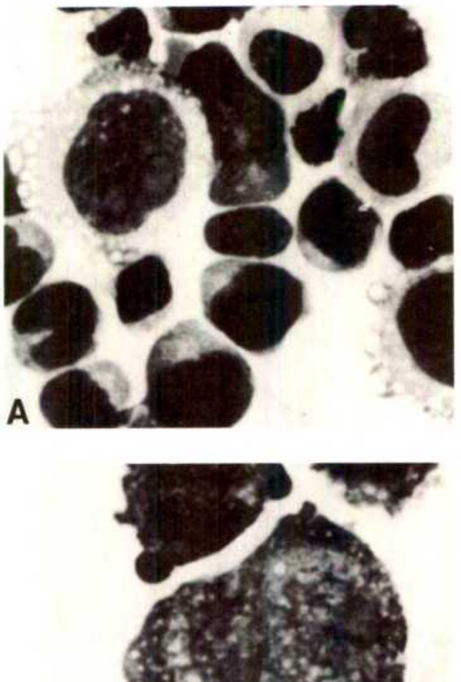

Fig 2. (A) Atypical cells in the original pleural effusion (May-Grünwald-Giemsa, original magnification ×1000; current magnification ×650). (B) A binucleated culture cell with conspicuous nucleoli (May-Grünwald-Giemsa, original magnification ×2,000; current magnification ×1,300).

Phagocytic Activity Tests

The India ink test was performed as previously described.[41] Phagocytic activity of the cell preparations used for the detection of $Fc\gamma$ and C3b receptors was also examined after a 1-hour incubation at 37 °C.

Heterologous Transplantation in Nude Mice

One million viable cells in 100 μL were inoculated into the subcutaneous tissue of 8-week-old mice.

Molecular Genetic Analysis

DNA extraction. Cells were lysed in STE (0.1 mol/L of NaCl, 10 mmol/L of Tris-HCl pH7.4, and 1 mmol/L of EDTA), 500 μg/mL proteinase, and 0.5% sodium dodecyl sulfate (SDS). After incubation, lysate was extracted twice with STE-saturated phenol and then precipitated with ethanol. After treatment with RNase (100 μg/mL) and proteinase K, DNA was re-extracted from the precipitate with STE-saturated phenol and precipitated with ethanol. DNA was dissolved in TE (10 mmol/L of Tris-HCl, pH7.4 and 1mmol/L of EDTA) and stored at 4 °C.

Southern blotting. DNA was digested with *Bam*HI or *Eco*RI, size-fractionated by agarose gel electrophoresis, and transferred onto nitrocellulose paper by the method of Southern.[42]

Preparations of labeled probe DNA. The 3.4-kb *Eco*RI-*Hind*III fragment of the joining region of the heavy chain gene and the 2-kb SacI–SacI fragment of the joining region of the κ chain gene were used as J_H and Jk probes, respectively. The 3-kb *Eco*RI-*Hind*III fragment of the constant region of the T cell receptor β chain was also used as a $C\beta_1$ probe.[43] Nick-translated, ^{32}P-labeled probes were hybridized to nitrocellulose filters in 5 × Denhardt's solution, 0.9 mol/L NaCl, 50 mmol/L of phosphate buffer (pH 7.7), and 5 mmol/L of EDTA, at 65 °C. After hybridization, the washed filters were exposed to film.

RESULTS

Morphological Findings

The KM-H2 cells appeared as clusters of large, nonadherent cells without villi in phase-contrast microscopy. In May-Grünwald-Giemsa-stained cytocentrifuge preparations, these cells had one to three round to oval nuclei with conspicuous nucleoli. Their cytoplasms were stained palely to moderately basophilic and sometimes contained vacuoles (Fig 2B). Their appearance was similar to that of the original pleural effusion cells.

Immunofluorescence Tests for EBNA

The KM-H2 cells were tested in triplicate for EBNA. All observations were negative.

Cytogenetic Findings

The established cell line was composed mainly of cells with 49 to 67 chromosomes, with a minor population having 44, 88, or >100 chromosomes. Karyotypes of KM-H2 cells were highly complex and unstable; however, they were compatible with those of the parental pleural effusion cells, which had near triploid and polyploid sets (Fig 3A). The banded analysis revealed various structural and numerical chromosome aberrations as shown in Fig 3B. The clonal origin of the KM-H2 cell line was ascertained by identifying common marker chromosomes: 5p+, 6p+, and 14p+. Ten years after the initial cultivation, the 5p+, 6p+, and 14p+ chromosomes were still preserved in all KM-H2 cells.

Cytochemical Findings

The original pleural effusion cells were negative for peroxidase reaction.

Enzyme cytochemistry (Table 2) did not demonstrate any peroxidase, alkaline phosphatase, or naphthol AS-D chloroacetate esterase activity in the KM-H2 cells. A weak reaction for acid phosphatase and α-naphthyl acetate esterase was observed in the paranuclear regions of most cells. In a few cells, these reactions were distributed throughout the cytoplasm.

Immunologic Marker Analysis

By immunostaining of the lymph node biopsy from the patient, the SR and H cells were stained distinctly for Leu-M1 and faintly for peanut agglutinin. They were negative for cytoplasmic lysozyme, α1-antitrypsin and S100 protein. Moreover, the KM-H2 cells revealed the same staining pattern as these SR and H cells in situ (Table 3).

Table 1. Polyclonal and Monoclonal Antibodies Used in This Study

Antibody	Specificity/Antigen	Source/Reference
OKIa1 (Mo-Ab)	HLA-DR antigen	Ortho[19]
OKT3 (Mo-Ab)	T cell	Ortho[20]
OKT4 (Mo-Ab)	Helper/inducer T cell	Ortho[20]
OKT6 (Mo-Ab)	Intrathymic T cell; Interdigitating cell	Ortho[20,21]
OKT8 (Mo-Ab)	Suppressor/cytotoxic T cell	Ortho[20]
OKT9 (Mo-Ab)	Transferrin receptor	Ortho[22]
OKT11 (Mo-Ab)	Sheep erythrocyte receptor	Ortho[23]
OKM1 (Mo-Ab)	Monocyte; granulocyte	Ortho[24]
Leu-1 (Mo-Ab)	T cell	Becton Dickinson[25]
Leu-7 (Mo-Ab)	NK cell	Becton Dickinson[26]
Leu-11 (Mo-Ab)	NK cell	Becton Dickinson[27]
Leu-M1 (Mo-Ab)	Monocyte, granulocyte	Becton Dickinson[28]
MCS1 (Mo-Ab)	Granulocyte	Provided by Dr Sagawa[29]
MCS2 (Mo-Ab)	Monocyte, granulocyte	Provided by Dr Sagawa[29]
My4 (Mo-Ab)	Monocyte	Coulter[30]
My7 (Mo-Ab)	Monocyte, granulocyte	Coulter[30]
J5 (Mo-Ab)	Common ALL antigen	Coulter[31]
B1 (Mo-Ab)	B cell	Coulter[32]
Ki-1 (Mo-Ab)	Sternberg-Reed cell	Provided by Dr Stein[33]
R10 (Mo-Ab)	Glycophorin	Provided by Dr Greaves[34]
R4/23 (Mo-Ab)	Dendritic reticulum cell	DAKO[35]
2D1 (Mo-Ab)	Leukocyte	Becton Dickinson[36]
Rabbit anti-TdT Ab	TdT	Provided by Dr Bollum[37]
Rabbit anti-lysozyme Ab	Lysozyme	DAKO
Rabbit anti-α1-antitrypsin Ab	α1-antitrypsin	DAKO
Rabbit anti-S100 protein Ab	S100 protein	Provided by Dr Watanabe[16]
Goat anti-human Ig Ab (F(ab')$_2$ fragment)	Human Ig	Cappel
Goat anti-mouse Ig Ab (F(ab')$_2$ fragment)	Mouse Ig	Cappel

Ig, immunoglobulin; Ab, antibody; Mo-Ab, monoclonal antibody; TdT, terminal deoxynucleotidyl transferase.

As demonstrated in Table 4, the reactivity of the KM-H2 line was almost identical to that of the SR and H cells in the fresh biopsy material reported by others.[45-48] They expressed Ki-1, Leu-M1, HLA-DR antigens and receptors for T cells, transferrin, C3b, and Fc portion of IgG, but lacked markers characterizing B cells (surface Ig, cytoplasmic Ig, B1), T cells (receptors for sheep erythrocytes, Leu-1, OKT3, OKT4, OKT6, OKT8), monocytes (OKM1, MCS2, My4, My7, lysozyme, α1-antitrypsin), dendritic reticulum cells (R4/23), IR cells (OKT6, S100 protein), and NK cells (Leu-7, Leu-11, OKM1). The expression of MCS1 antigens is also compatible with the above results because granulocyte-specific antigens, such as TÜ9, 3C4, and VIM-D5, are detected in freshly obtained SR and H cells.[6]

Phagocytic Activity

The KM-H2 cells did not exhibit phagocytosis of C3b-coated zymosan beads or IgG-coated erythrocytes or India ink particles.

Heterotransplantation in Nude Mice

Subcutaneous inoculation of the KM-H2 line failed to induce tumors in five attempts.

Molecular Genetic Analysis

Figure 4 shows the results of Southern-blot analysis of the immunoglobulin genes and the T cell receptor genes. The J_H segment of *Bam*HI-digested DNA from the KM-H2 cells was observed as a single band at 10-kb, indicating the presence of a heavy chain gene rearrangement; the Jk segment digested by *Bam*HI was detected at 10 kb, however, and was considered as a germline of the κ chain gene. Gene rearrangement of the T cell receptor β chain did not occur in the DNA digested with *Eco*RI or *Bam*HI.

DISCUSSION

In an effort to determine the origin of the SR and H cells in Hodgkin's disease, many investigators have attempted the establishment of permanent cell lines from tissues and body fluids of patients with Hodgkin's disease, but whether the cell lines established derived from SR or H cells seems to be open to question. In fact, several authors[49,50] appear to have erroneously identified the overgrowth of EBV-transformed lymphoblastoid cells as SR and H cells because of their morphologic similarity. Moreover, Harris and colleagues[51] have recently proved that several lines are not related to Hodgkin's disease but are non-human contaminants.

Three other cell lines deserve further discussion. One is the

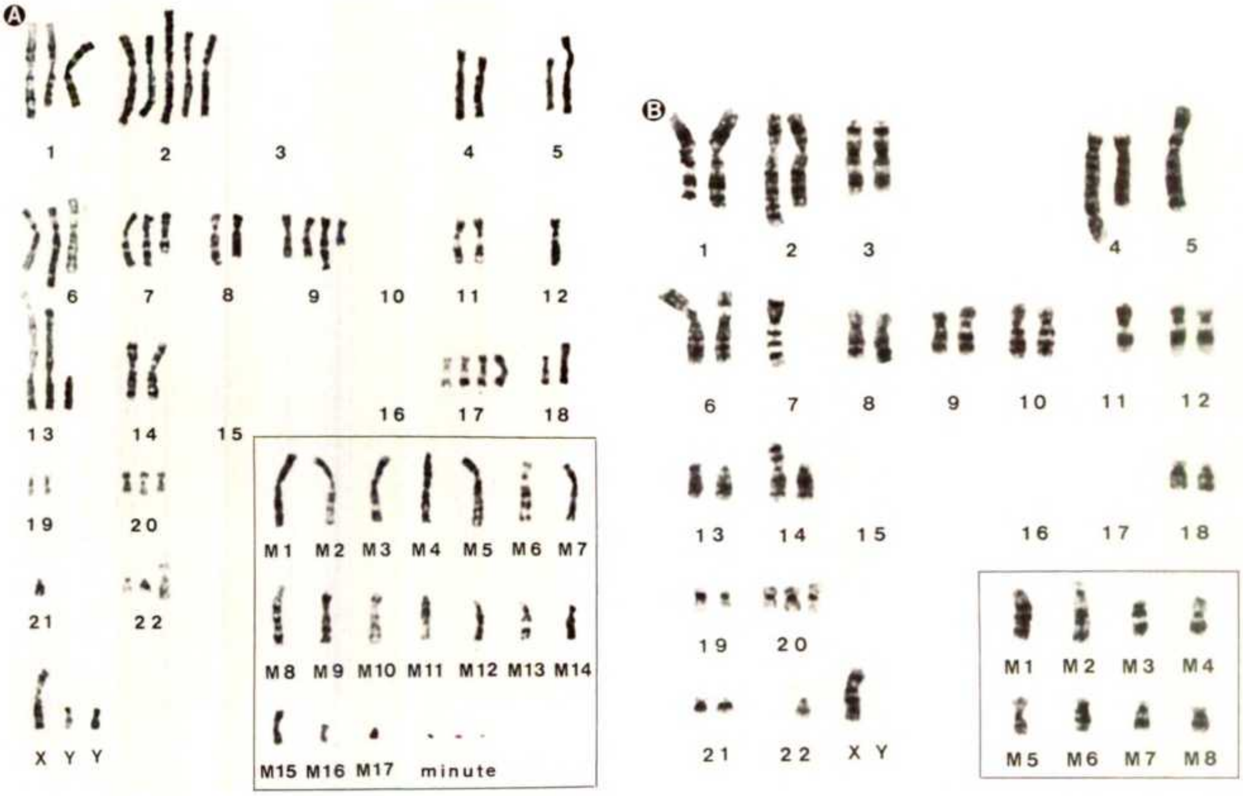

Fig 3. (A) G-banded karyotype of the pleural effusion cell in the triploid range: 70,XY,+Y,−3,−3,−10,−10,−12,−15,−15,−16,−16,+20,−21,+22,i(1q),+1q−,+i(2q),+2×2q−,5p+,6q+,+6p+,+7q−,8q−,+9q+,+9q−,13p+,+13p+,2×14p+,+2×17p+,18p+,+17mar,+3min. (B) G-banded karyotype of a hypodiploid KM-H2 cell in the 50th passage: 44,X,−Y,−5,−7,−11,−15,−15,−16,−16,−17,−17,+20,−22,2q+,4q+,5p+,6p+,7q+,10p+,14p+,+8mar. Unidentified marker chromosome of M1, M3, and M5 appear to be compatible with those of M8, M13, and M15 in (a), respectively. The 5p+, 6p+, and 14p+ chromosomes are preserved in continuously cultured KM-H2 cells for >10 years.

SU/RH-HD-1 cell line described by Olsson and co-workers.[41] The neoplastic nature of this line is apparent from the presence of chromosomal aberrations and the absence of the EBNA reaction. Its human origin is also indicated by the presence of the "alu" family in its DNA. However, the fact that this line does not react with Ki-1 or Leu-M1, which is reported to stain SR and H cells from all cases of Hodgkin's disease, obscures its relation to the SR and H cells.

The other cell line, established by Poppema and colleagues,[52] is the DEV cell line. Their extensive studies clearly indicate this line's neoplastic nature and its close relation to the SR and H cells in the patient's lymph node, but the atypical immunologic phenotype of the original SR and H cells, such as staining with B1 or anti-$\alpha 2$ chain antibody, seems to restrict its importance as a representative of the SR and H cells.

Another cell line, L428, has been reported by Schaadt and co-workers.[9] It was grown from the pleural effusion of a patient with advanced Hodgkin's disease of nodular sclerosing type. Its malignant nature is apparent from multiple structural and numerical chromosome abnormalities associated with a monoclonal pattern of multiple marker chromosomes. In addition, its cytochemical and immunologic features were identical to those of the SR and H cells in the fresh biopsy materials. Therefore, this line appears to be the only one hitherto proved to be derived from the SR and H cells.

*Data for SR and H cells are taken from previous reports.[45-48]

†Tested by the immunoperoxidase method.

Our KM-H2 cell line was established from the pleural fluid of a patient whose diagnosis was histologically confirmed by two independent pathologists. This diagnosis was supported by the finding that the "SR and H cells" in the patient's lymph node were distinctly positive for Leu-M1.[14] This line's neoplastic nature was indicated by the presence of structural and numerical chromosome aberrations and by the absence of the EBNA reaction, although tumor formation after subcutaneous inoculation of KM-H2 cells was not observed. Moreover, the KM-H2 cells showed the same immunostaining pattern as the SR and H cells in the patient's lymph node and shared nine positive properties and a number of negative properties with the SR and H cells in the fresh biopsy materials reported by other authors[44-48] (Tables 2 and 4). The cells also retained some of the chromosomal abnormalities observed in the pleural effusion cells. Thus, it seems reasonable to conclude that the KM-H2 cell line originated from the SR and H cells of Hodgkin's disease.

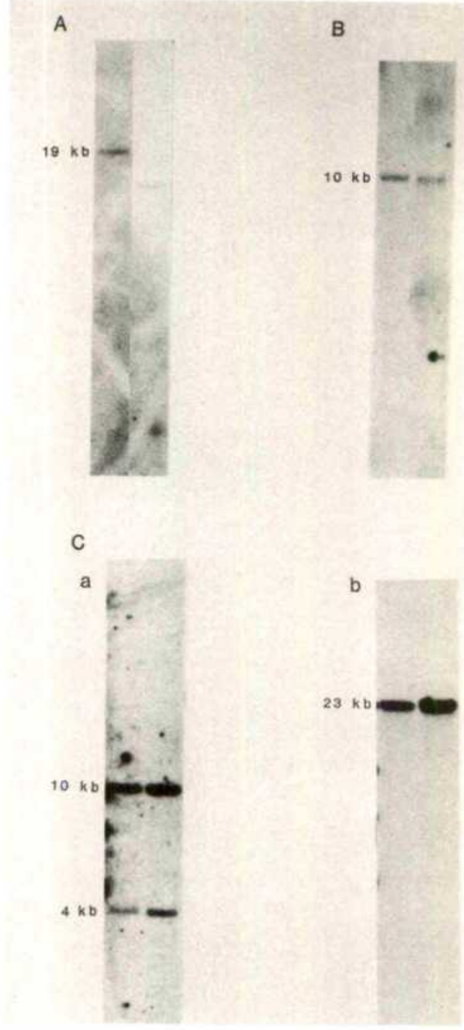

Fig 4. Southern-blot analyses of KM-H2 cells with Ig J_H (A), Ig Jk (B) and T cell receptor Cβ1 (C) as probes. In Figs 1 through 4, left lanes are controls: (A, B) T cell line MT-2; (C) B cell line BALL-1. Right lanes are KM-H2. (A) Germline Ig J_H segment is represented by 19 kb when digested with *Bam*HI; (B) germline Ig Jk segment is shown by 10 kb when cut with *Bam*HI. (C) (a) Ten kilobases and 4 kb correspond to the germline T cell β chain constant region genes, Cβ1 and Cβ2, respectively, when digested with *Eco*RI; (b) 23 kb represents the germline configuration of T cell receptor β chain gene, including Cβ1 and Cβ2 when cut with *Bam*HI.

Recent advances in molecular biology have made it clear that somatic recombinations of the immunoglobulin genes occur in B cell ontogeny. Korsmeyer and co-workers[53,54] proposed a model of genetic maturation in human B cell lineage and revealed that analysis of the immunoglobulin gene rearrangement was useful to determine the origin of leukemias and lymphomas.[55] Recently, several authors[56,57] have also reported that the T cell antigen receptor genes have a genomic structure similar to that of the immunoglobulin genes and that somatic recombinations of these genes take place in T cell differentiation. Because T cell receptor gene rearrangement is expected to occur only in T cell lineage, the analysis of this gene appears useful to identify the cellular origin of hematopoietic tumors.[58,59] Therefore, we used these molecular genetic approaches to analyze the cellular origin of the KM-H2 line, which is still obscure in spite of extensive cytochemical and immunologic studies.

The J_H region of the immunoglobulin genes in this line was rearranged, but not the Jk region or the constant region of the T cell receptor β chain genes. The germline configuration of the T cell receptor β chain genes, as well as the lack of the T cell antigens, virtually excludes the possibility of its T cell origin. However, the presence of only J_H recombination is not sufficient to conclude that it is of B cell lineage, since such a genomic pattern is also observed in some myelogenous leukemia cells.[60,61]

Indeed, the following observations favor its origin from the nonlymphoid cell lineage rather than from the B cell lineage, in contrast to recent reports[52,62] that support the B cell origin for the nodular sclerosing subtype of Hodgkin's disease: (a) The expression of common ALL antigens or TdT, which is usually observed at this stage of B cell differentiation, could not be detected in the KM-H2 cells; (b) neither cytoplasmic Ig nor B1 antigens could be induced by the presence of 4β-phorbol-12-myristate-13 acetate (TPA) (unpublished observations); (c) Leu-M1 and MCS1 antigens were expressed, and (d) a reaction for acid phosphatase and α-naphthyl acetate esterase was observed in most cells. Therefore, our results suggest the heterogenous cellular origin of Hodgkin's disease, especially among the histological subtypes, although further studies are needed.

ACKNOWLEDGMENT

We thank Drs M.F. Greaves, F.J. Bollum, H. Stein, S. Watanabe, and K. Sagawa for kindly providing monoclonal antibodies and antiserum; and Y. Katayama and E. Takaya for technical assistance.

α-Interferon Activates the Natural Killer System in Patients With Hairy Cell Leukemia

By G. Semenzato, G. Pizzolo, C. Agostini, A. Ambrosetti, R. Zambello, L. Trentin, M. Luca, M. Masciarelli, M. Chilosi, F. Vinante, G. Perona, and G. Cetto

To elucidate the mechanisms of α-interferon's (α-INF) therapeutic effect on clinical and laboratory findings in hairy cell leukemia, we sequentially monitored different immunologic parameters in three patients treated with recombinant α-INF. The most evident effect of this treatment on the immune system was the recovery of natural killer (NK) cell in vitro activity of peripheral blood lymphocytes, which was severely impaired before therapy. In particular, NK function began to improve after 3 months, and a complete recovery was obtained after 6 months in all cases. This increase parallels the improvement in clinical and laboratory findings.

HAIRY CELL LEUKEMIA (HCL) is a malignant B cell disorder usually characterized by isolated splenomegaly and peripheral pancytopenia associated with the presence in the blood of mononuclear hairy cells that infiltrate the spleen and bone marrow.[1,2] Although splenectomy has been the treatment of choice in this disease for a number of years, a large number of patients fail to respond to this approach.[2] The use of different therapeutic strategies based on chemotherapeutic agents has been unsatisfactory.[3] A highly effective treatment of these patients has been recently offered by α-interferon (α-INF)[4-7]; however, the mechanisms that account for its therapeutic efficacy are unclear. In particular, no information has been provided thus far on the possible modifications of immunologic parameters induced by α-INF treatment, which may correlate with the improved clinical and laboratory findings in HCL-treated patients.

Interferons are powerful stimulants of natural killer (NK) cell activity,[8] and this seems to be the mechanism of INF antitumor action in the animal model.[9] On the other hand, severe deficiency of NK function has been demonstrated in HCL-untreated patients.[10,11] The aim of this study was to monitor different immunologic parameters sequentially in HCL patients treated with recombinant α-INF (rINF-α_2). Special attention was paid to the phenotypic and functional analysis of NK cells, and these findings have been related to the modifications observed on the clinical and laboratory parameters. A 9-month follow-up was taken into account.

MATERIALS AND METHODS

Patients. Three patients (two males and one female aged 64, 44, and 64 years, respectively) with HCL were treated with rINF-α_2 obtained from the Schering Corp (Shering, Italy) as lyophilized powder (5×10^6 IU/vial) and reconstituted with sterile water. Informed consent was obtained from all patients, who had been advised of procedures and attendant risks. The diagnosis of HCL was based on clinical, morphologic, and cytochemical criteria[1,2]; none of the patients had a splenectomy or previous treatment. Before rINF-α_2 therapy, a severe neutropenia ($<500/\mu L$) was present in all patients; two of them also had thrombocytopenia and mild anemia (Fig 1). The treatment started in Nov 1984 and consisted of 2×10^6 IU/m^2 of rINF-α_2 injected subcutaneously three times a week. Adverse reactions of moderate intensity consisting mainly of fever that was controlled by acetaminophen were seen in two patients. A severe neutropenia with septic fever developed in one patient during the fourth week of treatment, requiring interruption of rINF-α_2 administration for 40 days.

Separation procedures. Mononuclear cells were obtained from freshly drawn heparinized peripheral blood by centrifugation on Ficoll/Hypaque gradient. The cells were washed three times and resuspended in RPMI 1640 (GIBCO, Grand Island, NY). Adherent cells were removed by two sequential incubations for 45 minutes in plastic Petri dishes at 37 °C in an atmosphere of 95% air and 5% CO_2.

Phenotypic analysis. The following monoclonal antibodies (MoAbs) were used in this study: OKT3 (Ortho Pharmaceutical, Raritan, NJ) reacts with mature T cells[12]; OKT4 and OKT8 (Ortho) selectively bind to T lymphocyte subsets including cells with helper and suppressor/cytotoxic activity, respectively[12]; HNK-1 (Leu-7, Becton-Dickinson, Sunnyvale, Calif) defines a differentiation antigen expressed on NK and K cells[13]; and anti-Tac (kindly provided by Dr T. Uchiyama, Kyoto, Japan) has been found to recognize the membrane receptor for interleukin 2 on T and B cells[14] and on hairy cells.[15]

Nonadherent cells obtained as described were incubated for 30 minutes at 4 °C with the aforementioned reagents. Following incubation, cells were washed three times, and a fluorescein-conjugated F(ab)$_2$ goat antimouse immunoglobulin antiserum (Cappel Laboratories, Cochranville, Pa) was added for 30 minutes at 4 °C. After further washing, 300 cells were examined under a Leitz Orthoplan microscope (Wetzlar, FRG) equipped for epifluorescence.

Enzyme histochemistry and immunohistology of bone marrow biopsies were performed according to the method previously described in detail by using a series of markers, including tartrate-resistant acid phophatase, RFB-4, anti-Tac, and anti-HLA-DR MoAbs.[16]

Functional evaluations. NK activity was assessed by lysis of ^{51}Cr-labeled K-562 target cells as previously described.[17] Briefly, target cells were labeled overnight at 37 °C in 5% CO_2 with 100 μCi $Na^{51}CrO_4$ (CEA IRE Sorin, Biomedica, Saluggia, Italy), extensively washed three times before use, and then adjusted to a final concentration of 10^5 cells/mL in RPMI 1640 supplemented with 10% fetal calf serum (FCS) (Microbiological Products, Wakersville, Mass). To perform the test, 100 μL of labeled targets (10^4 cells) were cocultured with effector cells for four hours at 37 °C in 5% CO_2 at different dilutions to final ratios between effectors and target cells (E/T): 5:1, 10:1, 20:1, 40:1, and 80:1 in triplicate round-bottom wells (Limbro plates Limbro, Hamden, Conn). Triplicate wells with

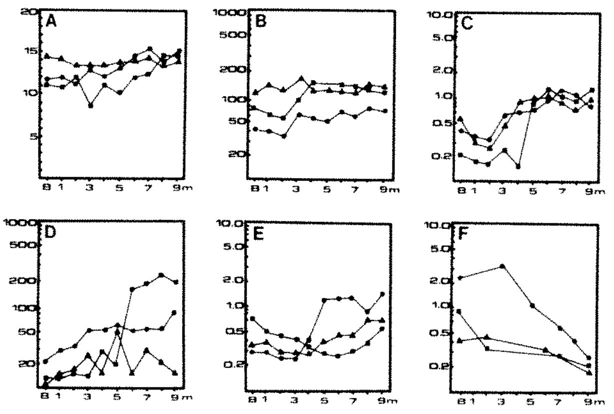

Fig 1. Peripheral blood findings before (B) rINF-α_2 therapy and during the follow-up at 1, 2, 3, 4, 5, 6, 7, 8, and 9 months (m). ▲, ●, and ■ represent individual patients (F.N., M.R., and P.A., respectively). (A) Hemoglobin (gr/dL), (B) Platelets (× 10^{-3}), (C) Neutrophils (× 10^{-3}), (D) Monocytes, (E) Lymphocytes (× 10^{-3}), (F) Hairy Cells (× 10^{-3}).

target cells in medium alone and in detergent were assessed to determine spontaneous and maximum release, respectively. Following this incubation supernatants were harvested and counted in a gamma counter. The mean value of triplicate assays was used to calculate the percentage of cytotoxicity according to the formula: percent cytotoxicity = (cpm release in test − cpm spontaneous release)/(cpm maximum release − cpm spontaneous release) × 100. Spontaneous release from the target cells was always less than 8%.

The proliferative response to phytohemoagglutinin (PHA) was evaluated as previously described.[17]

Twenty age-matched healthy volunteers were used as controls. All data are expressed as the mean ± SE of the mean. Statistical analyses were performed by the Cochran-Cox test.

RESULTS

Figure 1 shows the changes in peripheral blood counts in individual patients following rINF-α_2 treatment. Two patients had an improvement of their anemia and thrombocytopenia. With regard to WBC, the neutropenia dramatically improved in all cases, and the number of monocytes showed a net increase in two cases (M.R., P.A.). Lymphocytes increased in two out of three patients (M.R., F.N.). The number of hairy cells in the peripheral blood, as determined by morphology both on May-Grunwald-Giemsa–stained smears and phase-contrast examination of cells in suspensions, decreased in all patients.

Bone marrow biopsies performed after 3 and 7 months of rINF-α_2 therapy revealed an increase of the myeloid component in all patients. A marked reduction of hairy cell infiltration was observed in one case (P.A., from 90% to 20%), whereas in the two other cases, the frequency of hairy cells, although diminished, continued to represent a consistent proportion of the bone marrow cells (70% to 80%).

The evaluation of immunologic markers (Fig 2) shows a slight but not significant decrease of the T4/T8 ratio. Although the frequency of cells with an NK-related phenotype, as determined by the HNK-1 MoAb, increased in all patients (Fig 2), the absolute numbers of these cells were consistently within the normal range (<390/µL) in all cases.

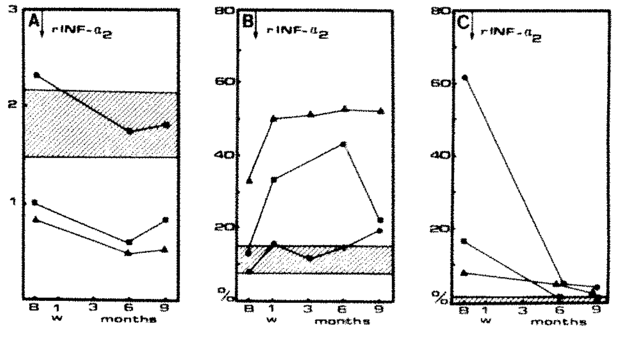

Fig 2. Phenotypic analysis of peripheral blood mononuclear cells with MoAbs before (B) and after 1 week ($\underset{w}{1}$) or 3, 6, and 9 months of rINF-α_2 therapy. Shaded areas represent the range values for controls. ▲, ●, and ■ represent individual patients (F.N., M.R., and P.A., respectively). (A) T4/T8 Ratio, (B) HNK-1 Positive Cells, (C) Anti-TAC Positive Cells.

The percentage of Tac-positive cells was reduced in all patients according to the decrease of the number of hairy cells.

Analysis of NK in vitro function (Fig 3) demonstrated an initial decrease, at different E:T ratios, following the first months of rINF-α_2 therapy. NK function began to increase after 3 months, and complete recovery was observed after 6 months in all cases. At the 9-month evaluation, results were comparable with those obtained at the 6-month evaluation. Interestingly, the best response was observed in patient M.R. whose cells expressed the highest frequency of Tac$^+$ cells before treatment.

PHA-induced blastogenesis was reduced with respect to controls and did not reveal significant differences during the follow-up of patients.

DISCUSSION

We have demonstrated that the treatment of HCL with rINF-α_2 restores the NK cell system, which is severely depressed in these patients before α-INF therapy. This parallels the improved clinical and laboratory findings.

α-INF belongs to a large family of biologic response-modifying drugs whose activity includes an antiviral effect, a direct cytotoxic property, and a cell differentiation function.

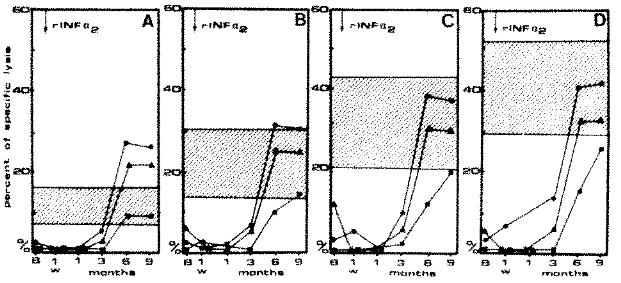

Fig 3. NK in vitro activity before (B) the rINF-α_2 activity and during the follow-up at 1 week ($\underset{w}{1}$) and 1, 3, 6, and 9 months. Shaded areas represent the range values for controls. ▲, ●, and ■ represent individual patients (F.N., M.R., and P.A., respectively). (A) 10:1 E:T Ratio, (B) 20:1 E:T Ratio, (C) 40:1 E:T Ratio, (D) 80:1 E:T Ratio.

α-INF has been used in several neoplastic disorders,[18,19] and as a matter of fact, the best response has been observed in HCL patients.[20] However, no complete and longitudinal studies are available that document the effects of α-INF therapy on different immunologic parameters in this disease. For one thing, our data confirmed previous studies demonstrating that the NK activity in these patients is impaired.[10,11] Since the defect of NK function persisted even when these cells were isolated from other cell populations (ref 11 and our unpublished results), the impairment of cytotoxic function cannot be consequent to cellular dilution. Following rINF-α_2 therapy, the NK function initially decreased, but after 3 months the values began to improve and definitely recovered after 6 months.

NK cells have been thought to play a significant role in the host defense mechanisms involved in the resolution of certain infectious agents and in tumor rejection.[21] Furthermore, several lines of evidence demonstrate that NK cells can directly lyse tumor cells,[22] especially following interferon activation,[23] and can inhibit clonogenic growth of fresh leukemic cells.[24] A lack of production of endogenous α-INF in HCL, possibly resulting from chromosomal abnormalities,[4] could be involved in the defective NK function. Therapy with rINF-α_2 could restore a mechanism that currently takes place normally in the host's defense against foreign insults and/or in the control of tumor growth.

Since interleukin 2 (IL 2) activates NK cells,[25] the severe deficency of NK activity reported in untreated HCL patients[10,11] could also be related to the impaired levels of IL 2 consequent to its absorbtion by hairy cells, which are equipped with IL 2 receptors.[15] In line with this interpretation, other neoplasms, ie, cutaneous T cell lymphomas usually characterized by the expression of IL 2 receptors,[26] are highly responsive to α-INF.[27] The two mechanisms mediated by IL 2 and α-INF might synergistically act on NK boosting.[28] Consistent with this latter interpretation, we found that before starting the rINF-α_2 therapy the incubation at 37 °C for 18 hours of peripheral blood cells from our patients both with rINF-α_2 and with recombinant IL 2 led to an enhancement of the NK in vitro function (data not shown).

The attribution of α-INF effects against tumor growth solely to its enhancement of NK function would be inappropriate. In fact, apart from the activation of NK cells, other mechanisms may be involved in patients affected by different disorders following α-INF treatment.[29] As a matter of fact, the association of other effects could account for the lack of correlation usually observed between clinical improvement and evaluation of the NK in vitro activity in patients other than those with HCL.[30-32] Differences in the type of α-INF, its schedule or route of administration, and especially the dose used could also be a source of discrepancy. In this regard, it has been recently demonstrated[33] that high doses of INF display a direct activity (ie, a cytopathic effect), whereas low doses increase the indirect power of this substance through an enhancement of the antitumor activity of the immune system (eg, the effectiveness of NK cell activation).[34-35] In this regard, evidence recently provided that α-INF enhances the expression of class II HLA antigens on hairy cells has led to speculation that α-INF might exert its antileukemic activity by potentiating a cytotoxic mechanism.[36] The good correlation between the clinical improvement and the NK in vitro function observed in our study suggests that the NK system plays a relevant role in α-INF–treated HCL patients. Thus, in some diseases (notably HCL) the activation of NK activity may be prominent, whereas in other disorders, the cytopathic effect may be the main mechanism involved in tumor growth control. The latter has been clearly demonstrated in some neoplastic conditions, especially using high doses of chemotherapy.[33]

Another effect of α-INF is its cell differentiation property.[37] In this regard, the improvement of neutropenia and bone marrow findings in HCL patients could be consequent to an effect on cellular differentiation either directly[38] or via different circuits involving activated cells.[39] This differentiation ability could also account for the increase in the monocytic component observed in two of our patients, similar to the results described by Territo et al[40] in cancer patients.

We conclude that α-INF therapy leads to a series of effects. Among these, at least in HCL patients, the improvement of NK cell activity might be crucial. Of course, the demonstration of a specific lysis of hairy cells by autologous cytotoxic cells will represent the final proof supporting the relevance of cytotoxic mechanisms in α-INF–treated HCL patients. The small number of patients and the short follow-up preclude firm statements regarding the impact of NK evaluation on the prognosis of these patients. We only want to emphasize that the analysis of immunologic parameters might help to clarify the possible therapeutic action of α-INF in HCL. Further studies on a large series of patients are needed to clarify whether evaluation of NK activity may be useful in predicting the prognosis and/or monitoring α-INF therapy by determining the optimal dose, schedule, and duration of treatment.

ACKNOWLEDGMENT

The authors wish to thank the Schering Corp (Schering, Italy) for providing the rINF-α_2.

Response to 2′-Deoxycoformycin After Failure of Interferon-α in Nonsplenectomized Patients With Hairy Cell Leukemia

By Kenneth A. Foon, Gordon M. Nakano, Charles A. Koller, Dan L. Longo, and Ronald G. Steis

Two patients with hairy cell leukemia with massive splenomegaly and severe pancytopenia were treated with recombinant α-A interferon (IFN-α-2a). There was no significant response to a trial of IFN-α-2a (11 and 20 weeks) with respect to blood counts or spleen size. Subsequent treatment with 2′-deoxycoformycin (dCF) for 8 consecutive weeks (4 mg/m^2/wk) resulted in normalization of spleen size and a normalization of peripheral blood counts and bone marrow in one patient. The second patient demonstrated a reduction in spleen size and improved blood counts following 9 weeks of dCF therapy but eventually became refractory. This demonstrates that dCF is non-cross-resistant with interferon and confirms the efficacy of dCF in nonsplenectomized patients.

© *1986 by Grune & Stratton, Inc.*

HAIRY CELL leukemia is a lymphoproliferative disorder generally involving B lymphocytes and usually presents with cytopenias and splenomegaly.[1,2] Standard initial therapy has been splenectomy, which often restores hematologic parameters to normal.[3-5] Unfortunately, most of these patients relapse with recurrent cytopenias weeks to years following splenectomy. Treatment with cytotoxic agents such as chlorambucil may result in a temporary reduction in tumor burden but are generally not very effective in improving granulocyte counts.[6] Recently, in a preliminary study using partially purified natural interferon-α at a dose of 3 × 10^6 units daily, three complete remissions and four partial remissions were observed in seven patients with hairy cell leukemia.[7] All seven patients had a recovery of peripheral blood counts. We and others have reported similar responses to recombinant interferon-α, with greater than 90% response rates.[8-10] Since most patients receiving interferon-α to date have had prior splenectomy, the clinical efficacy of interferon-α in nonsplenectomized patients remains uncertain.

Even more recently, the lymphocytotoxic agent, 2′-deoxycoformycin (dCF), or pentostatin, was reported to have induced rapid, complete remissions in two previously untreated, nonsplenectomized patients with hairy cell leukemia.[11] dCF is a tight-binding inhibitor of adenosine deaminase (ADA), the enzyme responsible for the conversion of adenosine to inosine and deoxyadenosine to deoxyinosine. In the absence of ADA activity, deoxyadenosine is phosphorylated to deoxyadenosine triphosphate (dATP) rather than deaminated to deoxyinosine, which may contribute to the lymphocytotoxicity.[12] The biochemical basis for this toxicity remains controversial, and recent studies have suggested that the principal cause of cell death in normal resting human lymphocytes is depletion of NAD.[13] The drug has been used successfully in the treatment of acute lymphoblastic leukemia, but has been associated with severe toxicity when used in higher doses.[14] Clinical nonlymphoid toxicity has been correlated with depletion of ATP[15] and with accumulation of dATP in red cells.[16,17] Further confirmation of the promising results with dCF in patients with hairy cell leukemia as well as the apparent lack of toxicity is needed, and the comparative efficacy of interferon-α *v* dCF in this disease remains to be demonstrated. We report the results of dCF therapy in two nonsplenectomized hairy cell leukemia patients who had failed prior therapy with recombinant α-A interferon (IFN-α-2a).

MATERIALS AND METHODS

Patient 1. The first patient was a 42-year-old Romanian male who was in apparent good health until March 1984 when he noted the insidious onset of fatigue, weight loss, and exertional dyspnea. These symptoms progressed, and in Aug 1984, he was admitted to the University of Michigan Medical Center with acute epistaxis.

Physical examination was significant for moderate epistaxis without an obvious source. The liver was enlarged with a 24-cm span, and the spleen was palpable 12 cm below the left costal margin. The remainder of his examination was unremarkable.

Initial laboratory data included a hemoglobin level of 4.9 g/100 mL, hematocrit value of 15.7%, and a platelet count of 41 × 10^9/L. The white blood count was 4.3 × 10^9/L with 14% neutrophils, 3% bands, 81% lymphocytes, 2% monocytes, plus 13 nucleated red cells. Most of the lymphoid mononuclear cells were noted to have bean-shaped nuclei and ragged cytoplasmic margins typical of hairy cells. Tartrate-resistant acid phosphatase stain was positive, and bone marrow biopsy results confirmed the diagnosis of hairy cell leukemia.

The epistaxis was controlled with local packing and transfusion of random donor platelets and packed red cells. Splenectomy was strongly recommended but was refused by the patient.

For the next month, the patient was treated supportively with platelets and packed red cells for recurrent epistaxis as well as with multiple antibiotics for episodes of fever. He continued to refuse splenectomy on repeated occasions.

In Sept 1984, the patient was referred to the Biological Response Modifiers Program of the National Cancer Institute. Following the patient's informed consent, he underwent a 12-week trial of IFN-α-2a (Hoffmann-La Roche Inc, Nutley, NJ) administered on a daily basis subcutaneously at a dose of 3 × 10^6 U/d from Sept 24 through Dec 11, 1984. Although during this period his epistaxis subsided and his transfusion requirements appeared to decrease somewhat, his severe pancytopenia and massive hepatosplenomegaly persisted. Due to a falling platelet count with recurrent petechiae and epistaxis, the interferon therapy was discontinued.

Six weeks after stopping IFN-α-2a therapy and following the patient's informed consent, he began to receive dCF at a dose of 4 mg/m^2/wk as an intravenous (IV) bolus followed by a liter of normal saline infused for a period of one to two hours. Allopurinol, 300 mg/d orally, was also given during the first week.

Patient 2. The second patient was a 65-year-old Pakistani woman who had had a 15-year history of splenomegaly ultimately diagnosed as hairy cell leukemia in 1979. She was treated with a number of courses of cytotoxic chemotherapy (chlorambucil and cyclophosphamide) but was not considered a good surgical candidate. She was referred to the National Cancer Institute for IFN-α-2a therapy. Physical examination was significant for a massively enlarged spleen (approximately 30 cm below the left costal margin). Her liver was palpable 9 cm below her right costal margin.

Initial laboratory data revealed a hemoglobin level of 11.5 g/100 mL, hematocrit value of 35%, and platelet count of 92 × 10^9/L. The WBC count was 133 × 10^9/L with 2% neutrophils, 0% bands, 0% monocytes, and 98% lymphocytes having the characteristic appearance of hairy cell leukemia cells. Tartrate-resistant acid phosphatase stain was positive, and bone marrow biopsy results confirmed the diagnosis of hairy cell leukemia.

On Dec 17, 1984, the patient began a daily dose of 3 × 10^6 units of rIFN-αA (informed consent was obtained prior to therapy). There were no changes in any of the laboratory or physical parameters throughout the course of 20 weeks of therapy. She was subsequently treated with dCF at a dose of 4 mg/m^2/wk as previously described (informed consent was obtained prior to therapy). Allopurinol therapy, 300 mg/m^2 orally, was also begun.

Measurement of intracellular adenine nucleotides. Red cell ATP and dATP were measured using previously reported techniques.[16]

Criteria for response. Complete remission was defined as the absence of hairy cells in the bone marrow aspirate and biopsy specimen, bone marrow granulocytes above 35%, and recovery of the hemoglobin level to $\geq$12 g/dL, the absolute granulocyte counts to $\geqq$1.5 × 10^9/L, and the platelet counts to $\geq$100 × 10^9/L for $\geqq$1 month. Partial remission was defined as a decrease of the hairy cell leukemia infiltrate by more than 50% from pretreatment levels and bone marrow granulocytes above 35%, with recovery of peripheral blood parameters as defined for complete remission for $\geqq$1 month. Minor remission was defined as a decrease of the hairy cell leukemia infiltrate by <50% from pretreatment values, bone marrow granulocytes of 25% to 35%, and improvement of peripheral blood parameters for $\geqq$1 month. Stabilization was defined as stabilization of all detectable abnormalities of bone marrow, peripheral blood, and physical examination. Progression was defined as the appearance of new, or worsening of preexistent abnormalities of peripheral blood, bone marrow, or physical examination. The duration of response was measured in terms of the number of days from the initial documentation of response to the documentation of progression.

RESULTS

No subjective or objective toxicity was observed during treatment with dCF in the first patient. Within 1 week after receiving his first dose of dCF, improvement was seen, with a decrease in liver and spleen size and reduction in circulating hairy cells. The platelet count and hepatosplenomegaly continued to improve progressively, and both parameters were within normal limits by week 8 of treatment (Fig 1). Also, by the eighth week of treatment, the absolute granulocyte count rose to 1 × 10^9/L (gradually rose to 2.6 × 10^9/L), and there were no longer visible hairy cells or nucleated erythrocytes on the peripheral blood film. Although he had no toxicity, the patient refused further therapy after week 8 because he was feeling well. Despite no further therapy, the patient's hematocrit value continued to improve and by week 16 was 41%. A bone marrow biopsy specimen showed normal hematopoietic cells without hairy cells. Red cell ATP remained within normal limits (135 to 156 [picomoles] pmol/10^6 cells), and red cell dATP rose no higher than 8.9 pmol/10^6 cells during treatment with dCF (data not shown).

The patient was lost to follow-up, but 7 months later agreed to return for an examination and blood count; he refused a bone marrow aspiration and biopsy. His hemoglobin level was 15 g/dL; hematocrit value, 45%; platelets, 114 × 10^9/L; and WBC count, 3.6 × 10^9/L (60% neutrophils, 10% bands, 29% lymphocytes, 1% monocytes). The peripheral blood smear revealed no hairy cell leukemia cells, but some very large abnormal appearing platelets were noted. His spleen was not palpable, and he had no physical complaints.

Patient 2 did not have a dramatic response to weekly injections of dCF but did have a rapid reduction in the circulating hairy cells from 179 × 10^9/L to 23 × 10^9/L during her ninth week of therapy, with improvement in her hematocrit value from 28% to 36% and stable platelet counts. Her spleen decreased in size from 30 cm to 16 cm below the left costal margin. A skin rash and keratoconjunctivitis developed in week 6, leading to a reduction of therapy to 4 mg/m^2 every other week for the next 12 weeks. Following this therapy, her white count increased, and she was given 4 mg/m^2 of dCF on two successive days. Her WBC count continued to rise despite stable hematocrit and platelets counts, and she was switched to chlorambucil treatment. She

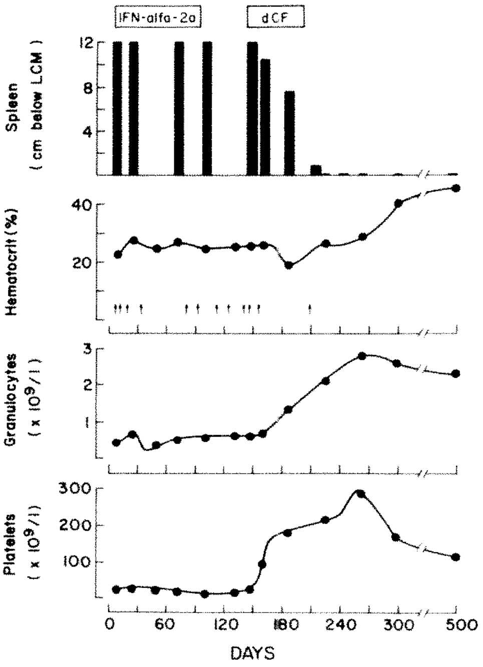

Fig 1. Clinical and laboratory parameters in patient 1 during and following interferon and dCF therapy. Arrows represent RBC transfusions. LCM, left costal margin.

did not respond to chlorambucil therapy and eventually was taken to surgery for a splenectomy. She had a transient minor response to splenectomy.

DISCUSSION

Within the past 2 years, two new therapeutic agents have shown exceptional promise for the treatment of hairy cell leukemia. Both interferon-α and dCF have been reported to induce complete remissions in this disease, with early results appearing far superior to conventional chemotherapeutic agents such as chlorambucil. Treatment-related toxicity has also been minor. Given the small numbers of patients reported, however, with only short-term observation, the relative efficacy of each of these agents remains uncertain with respect to extent of disease and prior therapy.

Neither of our patients had prior splenectomy. They received IFN-α-2a (11 and 20 consecutive weeks, respectively) but had no clear response to this therapy. Although these two patients may have eventually responded to interferon at the same dose or at increased doses, it was decided to discontinue the treatment because of progressive thrombocytopenia with fresh bleeding and petechiae in one patient and painful splenic infarcts in the other. Both patients were subsequently treated with dCF, a second investigational drug. After only eight weekly injections of dCF the first patient had a dramatic response, with normalization of peripheral counts and bone marrow and resolution of severe hepatosplenomegaly. Seven months later he had no hepatosplenomegaly and a normal hematocrit value. However, he had moderate leukopenia and thrombocytopenia suggestive of recurrent hairy cell leukemia in his bone marrow. Unfortunately, he refused a bone marrow aspiration and biopsy. The other patient had a transient improvement in blood counts and reduction in the size of her spleen. Preliminary data from Spiers and co-workers have confirmed the effectiveness of dCF in nonsplenectomized patients with hairy cell leukemia as well as its effectiveness after failure of interferon-α.[18]

The failure of these two patients to respond to IFN-α-2a, contrary to the extremely high response rates in most patients, cannot be accounted for with certainty. Given the low efficacy of other forms of adoptive or active immunotherapy in the presence of high tumor burdens in laboratory animal models, it is possible that these patients might have responded if they had undergone prior splenectomy or if treatment had been started earlier in the course of the disease. Suboptimal drug delivery to tumor sites or an intrinsic resistance of the patient's hairy cells to IFN-α-2a is also possible.

The optimum dose and frequency of dCF administration remains to be established. In phase I studies in acute leukemia, daily IV administration of dCF for three to seven consecutive days in doses of 0.15 to 1.0 mg/kg/d resulted in a fairly high incidence of gastrointestinal toxicity (nausea, vomiting, and diarrhea), with occasional keratoconjunctivitis nephrotoxicity, hepatotoxicity, CNS toxicity, or death.[16] The two hairy cell leukemia patients with complete responses to dCF reported by Spiers et al[11] initially received two or three consecutive daily IV boluses of dCF at a dose of 5 mg/m^2 followed by two consecutive days of treatment every 2 weeks for a total of 15 or 16 doses. Reported toxicity to lower doses of dCF was moderately severe nausea and vomiting in one patient and a transient photosensitivity rash in both patients. Our patients were treated with a lower weekly dose of 4 mg/m^2 without a loading dose. Despite the massive tumor burden, the rapidity of antitumor effect was nonetheless striking, and there was no demonstrable toxicity in one patient. The minimal increase in red cell dATP and decrease in ATP seen in this patient was consistent with the observed lack of toxicity.[17] The second patient did not have a dramatic response to dCF, and her therapy was complicated by rash and keratoconjunctivitis. Unfortunately, we did not measure red cell adenine nucleotides in this patient. The treatment schedule chosen for our patients as induction therapy thus appears to be a reasonable one with respect to safety and efficacy, although the long-term toxicity of dCF in hairy cell leukemia patients remains to be studied. Toxicity in patient 2 was improved when therapy was decreased to every other week.

In summary, we report one complete response and one minor response to dCF in two nonsplenectomized hairy cell leukemia patients following their failure to respond to IFN-α-2a. Weekly outpatient low-dose dCF therapy without a loading schedule was extremely well tolerated. These cases confirm the responsiveness of hairy cell leukemia to dCF in nonsplenectomized patients with high tumor burdens and suggest a possible superiority of dCF over interferon-α in this setting as well as a lack of cross-resistance with interferon. Unanswered questions still remaining include remission duration and survival in responders to interferon-α and dCF and the role of maintenance therapy using either interferon-α or dCF. Although the dramatic resolution of splenomegaly in patient 1 with dCF raises the question of whether splenectomy should continue as first-line therapy for hairy cell leukemia, further study of the safety and efficacy of dCF with longer follow-up will be necessary before dCF can be recommended as first-line therapy outside of the investigational setting.

CONCISE REPORT

The Percentage of Dense Red Cells Does Not Predict Incidence of Sickle Cell Painful Crisis

By Henny H. Billett, Kenneth Kim, Mary E. Fabry, and Ronald L. Nagel

To test the hypothesis that the tendency of hemoglobin S (HbS) to polymerize within cells is the major determinant of the incidence of vaso-occlusive episodes, we have examined the effect of the percentage of dense cells (as measured by Percoll-Stractan continuous density gradient centrifugation) on the frequency of painful crises in a group of 36 patients with sickle cell disease. No correlation was found between the percentage of dense cells and admissions for crisis. Among the patients with known α-gene status ($n = 25$), the strong correlation between decreased dense cells and α-thalassemia ($-\alpha/\alpha\alpha$) reported previously was confirmed ($P < .001$). In addition, in this small subset, patients with α-thalassemia ($-\alpha/\alpha\alpha$) appeared to have a marginally increased number of admissions for sickle cell crisis ($t = 2.1910$, $P < .05$), which was independent of the percentage of dense cells. We conclude that the percentage of dense sickle cells cannot predict the incidence of painful crisis, suggesting that other factors (microcirculatory regulation or other humoral and cellular factors) are more important in the generation maintenance of painful crises than the necessary, but not sufficient, tendency of HbS-containing red cells to sickle.

© 1986 by Grune & Stratton, Inc.

SICKLE CELL DISEASE is a clinically heterogeneous disorder arising from a single amino acid substitution in the hemoglobin (Hb) β-chain, which results in intracellular polymerization of deoxyhemoglobin S.[1] The heterogeneity may express itself by variation in the frequency of painful crises, extent of chronic end organ damage, degree of anemia, or, ultimately, in life expectancy. These varied components of severity may be under different pathophysiological controls, and variation might result from environmental or epistatic gene effects.[2] Sickling has been shown to be modified by cellular HbF content,[3] by the presence of β-thalassemia,[4] and by the mean cell hemoglobin concentration (MCHC).[5] The presence of α-thalassemia has been shown to affect the deformability of homozygous sickle cell anemia (SS) cells and the percentage of dense cells,[6,7] and more recently cation content and transport.[8] In this paper, we will consider the impact of one aspect of the hematologic heterogeneity, the percentage of dense red cells, on the frequency of sickle cell painful crisis. The dense cell fraction contains the largest proportion of irreversibly sickled cells and has been shown to be the most rheologically incompetent.[9] If these qualities of sickle cells are the major determinants of sickle cell painful crisis, as postulated by others,[10] the percent of dense cells should be correlated with the incidence of these episodes. The data presented here do not find that correlation, suggesting that microcirculatory and other physiologic events must be powerful modulators in the incidence of sickle cell painful crisis in patients with sickle cell anemia.

MATERIALS AND METHODS

Patient population. Thirty-six patients with sickle cell disease, followed for a minimum of three years (regardless of their painful crisis record) at the Albert Einstein College of Medicine Heredity Clinic, were chosen for this study. All blood samples were drawn when patients were in a clinical steady state. All patients were homozygous for HbS and 25 were characterized by their α-gene status; 13 of these patients also had concomitant deletional α-thalassemia ($-\alpha/\alpha\alpha$). The number of admissions was calculated from the medical records and confirmed by the patient and the responsible physician in most cases.

Patient characterization. Homozygosity for HbS was determined by two electrophoretic methods and a solubility test. Hematologic characteristics and family pedigree excluded S/β^0-thalassemia in most patients. Hemoglobin levels were determined in EDTA-anticoagulated blood on a Coulter S-plus. HbF levels were determined by agar gel electrophoresis[11] and by alkaline denaturation.[12] α-Gene determinations were performed by Dr Gregory Mears (Columbia Physicians and Surgeons, New York) and Dr Gisela Martinez (Albert Einstein College of Medicine, New York) as previously detailed.[7] Isopycnic red cell continuous density gradients were performed in patients without a history of crisis in the past three weeks, as described by Fabry and Nagel.[13] All statistics were done using a Daisy program on an Apple II computer.

RESULTS

Thirty-six patients (17 males and 19 females) were studied for a mean period ot 58.6 ± 16.5 months. Their average age was 34.6 ± 11.5 years. These patients were characterized by a mean hemoglobin level of 8.52 ± 1.66 g/dL with an average HbF level of 6.35% ± 5.35%. The average rate of admissions for painful crises was 1.64 ± 2.09 per year, and the mean percentage of dense cells was 19.2% ± 13.0%. Average length of stay of 337 hospitalizations was 7.63 ± 7.46 days.

The percentage of dense cells (Fraction 4 [F4]) levels ranged from 1% to 52%. The percentage of the dense cell fraction was not related to hemoglobin level ($r^2 = 0.001$). There was no significant correlation between F4 and the number of admissions for painful crisis ($r^2 = .076$, $F = 2.465$) (Fig 1). Twenty-five of our patients were analyzed for α-gene status; 13 patients had α-thalassemia ($-\alpha/\alpha\alpha$) and 12 patients had four α-genes. As reported previously,[7] there was a marked difference in the F4 levels between patients with three and four α-genes: patients with

α-thalassemia ($-\alpha/\alpha\alpha$) have a significantly lower dense cell fraction (11.6% ± 7.5% *v* 31.8% ± 11.8%, $t = 5.1538$, $P < .001$). Patients without α-thalassemia ($\alpha\alpha/\alpha\alpha$) showed a strong correlation of F4 with the percentage of HbF ($r^2 = .44$, $F = 7.56$, $P < .03$), but this was not true of those with α-thalassemia. The SS patients with α-thalassemia exhibited an average of three times the number of admissions per year when compared with the non-α-thalassemia group. The difference was marginally significant ($t = 2.1910$, $P < .05$). There was no significant difference in age or hemoglobin level in these two groups, although patients with α-thalassemia appear to have a slightly higher hemoglobin level. These results are listed in Table 1.

The average age of our population is much older than most sample groups of sickle cell patients. When we divided our patients into those 35 and over (n = 12) and those under 35 (n = 20) (the mean age for our group), it is apparent that age is not a factor in crises rate. Patients 35 and over had an average of 1.61 ± 2.60 admissions per year, whereas the younger group had 1.95 ± 2.18 admissions per year. Even patients over age 40 had an admission rate of 1.47 ± 0.82, again not a significant difference from the mean.

DISCUSSION

Only a few systematic attempts have been made to correlate red cell characteristics with painful crisis. Diggs[14] and Rieber et al[15] both reported on the percentage of irreversibly sickled cells during the course of crisis. More recently, Fabry and Nagel[13] have shown that although there is considerable heterogeneity in the percentage of dense cells for each particular patient, the percentage of dense cell fraction was constant (within 10%) during steady state.[16] During episodes of painful crisis, on the other hand, significant decreases in the percentage of dense cells were observed.[16] These findings do not mean that dense cells are indispensable for the generation of crises. We have observed a crisis in a patient who had been depleted of dense cells by a previous crisis,[16] and patients with S/β^0-thalassemia (characteristically exhibiting few dense cells) can also suffer from frequent painful crises. In accord with these observations, the results reported here indicate that there is no correlation between the percentage of dense cells and the incidence of sickle cell painful crises (Fig 1).

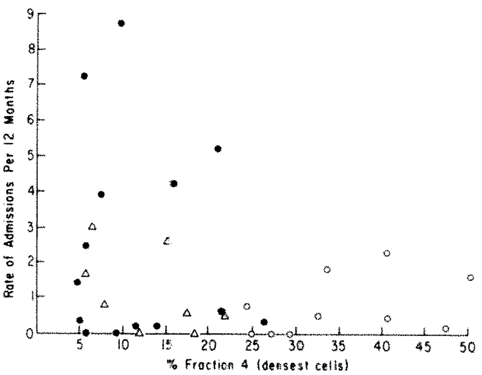

Fig 1. Admissions for painful crisis per year *v* percentage of dense cells (O—$\alpha\alpha/\alpha\alpha$, ●—$\alpha-/\alpha\alpha$, Δ—unknown α-globin gene status).

The percentage of dense cells was found to be strongly associated with ($-\alpha/\alpha\alpha$) thalassemia ($t = 6.805$, $P < 0.001$), in agreement with our previous report[7] and in contrast with the result of Noguchi et al,[17] who find this correlation significant only between ($-\alpha/-\alpha$) and ($\alpha\alpha/\alpha\alpha$) SS patients. Methodological differences in the detection and definition of the dense cell fraction, or differences in the genetic composition of the SS patient population[18] could explain the discrepancy.

Table 1. Effect of α-Gene Status on Several Clinical and Hematologic Parameters in SS Patients

N° α-Genes	3	4
n	13	12
age (yr)	35.69 ± 13.46	35.42 ± 10.69
F4 (%)	11.61 ± 7.48	31.82 ± 11.80*
Adm/yr	2.67 ± 2.96	0.73 ± 0.81†
Hb (g/dL)	9.02 ± 1.40	7.85 ± 2.05
HbF (%)	5.74 ± 5.39	5.23 ± 4.46

Adm/yr, number of hospital admissions for painful crises per year (minimum observation time, three years).

*$P < .001$.

†$P < .05$.

In our sample, SS patients with $-\alpha/\alpha\alpha$-thalassemia had more crisis admissions ($t = 2.191$, $P < 0.05$) than did patients without ($-\alpha/\alpha\alpha$) thalassemia. These marginally significant results are in contrast with published findings of Steinberg and the Cooperative Study of Sickle Cell Disease (CSSCD)[19] in a similar group of SS ($-\alpha/\alpha\alpha$) patients in which no differences were found in incidence of crises among patients with and without α-thalassemia. The ($-\alpha/\alpha\alpha$) sample size in both groups is small (13 in the present study *v* 39 in the CSSCD study). Larger samples defined by α-gene status and probably β-gene cluster haplotype[20] will have to be studied to settle this issue.

When all patients are considered, dense cell fractions appeared to be independent of the percentage of HbF. However, when a correlation was sought between the percentage of HbF and F4 within each of the α-gene groups, a strong correlation emerged between F4 and HbF levels in the non-α-thalassemic SS patient ($\alpha\alpha/\alpha\alpha$). Despite the fact that the HbF levels were virtually identical in both groups (5.74% *v* 5.22%), no correlation of the percentage of HbF and dense cells was seen in ($-\alpha/\alpha\alpha$) concomitant with SS disease, which suggests, as previously noted,[6] that the ameliorating effects of HbF and α-thalassemia are not additive.

The lack of correlation between the percentage of dense cells and the incidence of painful crises, reported here, is an important finding and strongly suggests that a reassessment of the major pathophysiologic determinants of this event is needed. It has been suggested that the propensity to polymerize within the sickle cell should be predictive of painful crises and other elements of severity.[10] This would imply that patients carrying the largest proportion of cells with high MCHC (and hence those most prone to polymerize and exhibit rheological incompetence) should have more frequent painful crises. We interpret our results to mean that, although necessary, the sickle cell is not sufficient to generate a vaso-occlusive episode. We propose that microcirculatory response to initial obstruction (neural or humoral), anatomical characteristics of the vasculature, perfusion pressure regimens, and related events may vary from patient to patient and within each patient from one microcirculatory bed to another. It is the interaction of all these components (some of which are probably under genetic control) that generates the considerable diversity in incidence of painful crises observed among sickle cell anemia patients.

CONCISE REPORT

Carbonic Anhydrase: A Marker for the Erythroid Phenotype in Acute Nonlymphocytic Leukemia

By Jami Walloch, Stanley Frankel, Mary Ann Hrisinko, and Susan C. Weil

Protein markers are often used to corroborate the morphological subtyping of hematopoietic malignancy. Most commonly, surface markers are used for the phenotyping of hematopoietic cells; however, internal proteins have also been used as markers. Glycophorin, hemoglobin A, hemoglobin F, and transferrin have all been used as markers for the erythroid phenotype. We have recently shown that carbonic anhydrase is constitutively and aberrantly expressed in two erythroleukemic cell lines. We here show that it is also present in high levels in primary erythroleukemic blasts and that it is a useful marker for the M6 phenotype when classifying acute nonlymphocytic leukemia.

© 1986 by Grune & Stratton, Inc.

IMMUNOHISTOCHEMISTRY is becoming increasingly more useful in the diagnostic categorization of acute leukemias. Most of the studies have been done on the acute lymphoblastic leukemias, in which a plethora of cell surface, cytoplasmic, and nuclear markers have been used for the characterization of lymphocyte type (B, T, or non-B, non-T cell) and degree of differentiation.[1-4] The acute nonlymphocytic leukemias (M1 to M6, according to the French-American-British [FAB] classification) are less well immunohistochemically characterized; however, a significant body of data involving granulocytic and monocytic markers are accumulating.[5,6] Much less phenotypic data have been gathered on the erythroleukemias (M6). This may be because so few leukemias are erythroleukemias: 95% of acute myeloid leukemias are M1 to M5; only 5% show early erythroid progenitors (M6).

Researchers have recently found erythroid markers useful in identifying early erythroid progenitors. The majority of the studies have been on hemoglobin (both adult and fetal) as a cytoplasmic marker.[7-9] Transferrin has also been used as an erythroid marker[8]; and Andersson et al[10,11] and Greaves et al[12,13] reported that a cell membrane glycoprotein, glycophorin A, is specific for erythroid cells and that glycophorin A appears early in primitive erythroid blasts.

Carbonic anhydrase (CA), the second most abundant protein in red blood cells, has been found at aberrantly high levels in early neoplastic erythroid blasts.[14,15] While three isoenzymes of CA are found in mammalian erythrocytes, the work herein deals exclusively with the most abundant isoenzyme, CAI. In normal human and murine erythroid progenitor cells, a gradual and parallel increase in both CA and globin is observed during maturation. By contrast, in a murine erythroleukemic cell line (Friend or MEL cells) and a new human erythroleukemic cell line (HEL cells),[16] CA is present at high levels in uninduced cells and does not change significantly with induction, whereas a marked increase in globin occurs with chemical induction. In this study, we ask whether this finding in two established continuous erythroleukemic cell lines can be extrapolated to primary human erythroleukemias and if CA may be an early cytoplasmic marker in human neoplastic erythroid cells. Herein, we report eight cases of erythroleukemia (FAB-M6) in which specimens were immunohistochemically stained for adult and fetal hemoglobin and CA.

MATERIALS AND METHODS

The B-5–fixed clot sections or bone core biopsies from eight patients with erythroleukemia (M6) diagnosed by classic morphological criteria[17] were retrieved from cases diagnosed between 1977 and 1985. Also, the B-5–fixed clot sections from five cases each of M1 and M2 acute myelogenous leukemia were obtained. A modified avidin–biotinylated peroxidase complex immunohistochemical staining technique[18] was used in an attempt to classify blast cells with respect to erythroid markers. Rabbit antiadult hemoglobin, antifetal hemoglobin, and anti-CA antibodies were used. The antihemoglobins (adult and fetal) were obtained from Dako (Santa Barbara, Calif); the anti-CA was produced in our laboratory as previously described.[15] Briefly, New Zealand white rabbits were injected subcutaneously with 1 mg of CA-I (Sigma Chemical Co, St Louis) emulsified in an equal volume of Freund's adjuvant. Booster injections were given at 14-day intervals; rabbit serum was collected 14 days after booster injections and assayed by immunoblot analysis with the antigen. Nonimmunized rabbit serum was used as a negative control.

Specimens from each case were stained by immunoperoxidase with all three antibodies, and for each antibody, 500 erythroid cells were evaluated for the degree of positive staining (0 through + + +). Each of these 500 cells was also evaluated for degree of maturity and classified as either early normoblasts or late normoblasts based on the degree of nuclear condensation.

RESULTS

The antihemoglobin antibodies and the anti-CA antibodies did not stain the blasts in the nonerythroid acute nonlymphocytic leukemias, M1 and M2. In these diseases, only rare residual late erythroid cells stained positively.

In the erythroleukemias, many of the cells stained positively. For each antibody, 500 erythroid cells were evaluated and divided into early or late normoblasts. For each of the eight cases, a larger percentage of the erythroid cells stained positively with the anti-CA antibody than with either the antiadult or the antifetal hemoglobin antibody. A typical case is shown in Fig 1. The percentages (average and range) of positively stained cells (in each category) for all eight

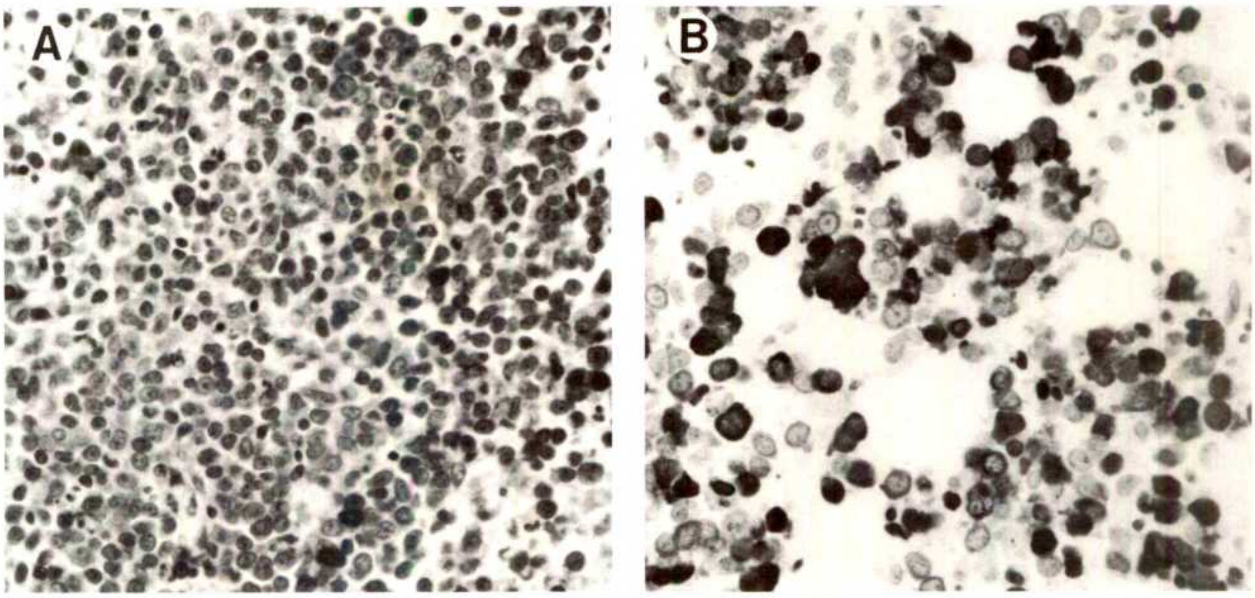

Fig 1. Immunoperoxidase staining with anti-CA on the paraffin-embedded clot section of (a) a case of acute myelogenous leukemia (M2) and (b) one of the eight erythroleukemia (M6) cases described in this study. (Original magnification ×500).

cases are shown in Table 1. The most striking result is that a significantly larger percentage of the early erythroblasts are strongly positive for CA than are positive for either of the hemoglobins (Table 1). This result indicates that the early neoplastic erythroblast has a high concentration of CA.

In the late erythroblasts, the number of cells positive for all three antibodies is similar, but the number intensely positive for CA is markedly higher than the number positive for the hemoglobin (Fig 1). These data suggest that although the production of hemoglobin increases during maturation of erythroblasts, the levels of CA in these neoplastic cells is initially high and remains high.

DISCUSSION

Although no previous work has examined primary erythroleukemic blasts with regard to CA expression, there is an extensive body of data on the CA expression in the peripheral blood cells of various hematologic malignancies. Several cases of juvenile chronic granulocytic leukemia have been described in which the mature red blood cells show a "reversion" to fetal erythropoiesis with high fetal hemoglobin levels and low CA levels.[21] In addition, three cases (polycythemia vera, acute myelogenous leukemia,[7] and erythroleukemia[9]) have been described in which the red cells show high fetal hemoglobin but discordant levels of CA.

Our earlier studies showed that CA is abundantly expressed in the early neoplastic erythroblasts of the erythroleukemia HEL and MEL cell lines in vitro.[15] This result led us to hypothesize that CA may be a more sensitive marker than hemoglobin for neoplastic erythroid cells in vivo. The results of this study (Table 1 and Fig 1) seem to corroborate our hypothesis. Anti-CA does not stain the nonerythroid acute nonlymphocytic leukemias (M1 and M2), but it does stain a significant number of M6 cells positively, especially in the early erythroblasts stage. Anti-CA seems to stain more cells positively in the early stage than does either adult or fetal antihemoglobin, especially if only the intensely staining cells are counted. And although the number of cells staining positively for all three antibodies is similar in the late erythroblast stage, if only the intensely staining cells are counted, anti-CA stains more cells positively than the antihemoglobin antibodies do.

Thus, the aberrant expression of CA has been observed both in vitro and in vivo in human erythroleukemias. The

	(128–315)	(185–371)	(34.0–92.4)	(9.8–71.7)	(23.1–66.8)	(10.5–46.5)

appearance of abnormally high levels of CA in erythroleukemia cells may be explained by a change in gene regulation. Debuire et al[19] described extensive sequence homology between the erb A gene of avian erythroblastosis virus and CA genes. It may be speculated that a mammalian oncogene exists that also has sequence homology with CA. An alternative hypothesis suggests that a translocation may juxtapose a CA gene in a manner analogous to the immunogloublin:c-myc (q8;q14) translocation in Burkitt's lymphoma.[20]

A case has been made for the usefulness of glycophorin A as a sensitive and specific marker for early erythroid blasts.[10,13] Greaves et al[12,13] and Andersson et al[10,11] have found glycophorin A particularly useful in reclassifying "cryptic" erythroleukemias that were previously classified as de novo poorly differentiated acute myeloid leukemias (AML) or as acute lymphocytic leukemias (ALL). True AML and ALL seldom express glycophorin A. However, the use of glycophorin A requires fresh patient material, which may not be available for a case that has been misclassified. Thus, CA has the advantage as a marker for cryptic erythroleukemias because it can be used on fixed, paraffin-embedded materials.

Our data indicate that CA is a useful marker for erythroleukemia. For classification of acute nonlymphocytic leukemias, it is specific for M6 and more sensitive than either adult or fetal hemoglobin. An added advantage of CA as a marker is that it can be used on fixed, paraffin-embedded file material. CA may thus be useful in confirming erythroid phenotype and reclassifying poorly differentiated AML and ALL as M6.

ACKNOWLEDGMENT

We thank Drs Steven Rosen and David Green for reviewing the manuscript and Dr Dante G. Scarpelli for help and support during the course of the work.

CONCISE REPORT

Platelet Membrane Microparticles in Blood Bank Fresh Frozen Plasma and Cryoprecipitate

By James N. George, Elaine B. Pickett, and Robert Heinz

Cryoprecipitate has been demonstrated to correct the bleeding abnormality of patients with some congenital (storage pool disease) and acquired (uremia) platelet abnormalities, but the reason for this effect is unknown. We found significant platelet contamination in plasma harvested to prepare fresh frozen plasma and cryoprecipitate. The platelet membrane microparticles produced by freezing and thawing of the plasma were highly concentrated in cryoprecipitate and may contribute to its therapeutic effect.

© 1986 by Grune & Stratton, Inc.

THE CRYOPRECIPITATE FRACTION of plasma can correct the bleeding abnormality of some patients with disorders of platelet function. The original observation was made in 1978, by Gerritsen et al,[1] who studied eight patients with congenital platelet storage pool deficiency. In each patient, the infusion of 16 bags of cryoprecipitate caused a shortening of the bleeding time, and four of these patients had surgical procedures during cryoprecipitate treatment with no excessive bleeding.[1] Infusion of pasteurized human albumin into six of the patients had no effect on the bleeding time.[1] This observation was extended by Janson et al[2] to the treatment of seven uremic patients. The bleeding time was decreased to normal, or nearly normal, in each patient after the infusion of ten bags of cryoprecipitate, and four of the patients underwent major surgery with no bleeding complications.[2] However, there was no control group in this study, and the risks of bleeding with surgery are unknown.

Although the explanation for this effect of cryoprecipitate is unknown, its use is commonly suggested in current textbooks.[3-7] The active principal in cryoprecipitate is believed to be a plasma component, and a potential advantage mentioned for its use in these patients is that platelet alloimmunization can be avoided.[1,7] However, the appearance of antiplatelet antibodies has been observed in patients with von Willebrand's disease treated only with cryoprecipitate (S.L. Pfueller, Monash University, Victoria, Australia, personal communication, October 1985), as well as in animals immunized with factor VIII–von Willebrand factor prepared from cryoprecipitate.[8] To determine if platelet-derived material is present in blood bank plasma products, we measured the platelet concentration in fresh plasma and the resulting platelet membrane microparticles[9,10] after the preparation of fresh frozen plasma and cryoprecipitate.

MATERIALS AND METHODS

Plasma samples were obtained from routine normal donors at the Medical Center Hospital Blood Bank, and plasma fractions were prepared by the Blood Bank personnel using standard methods described in the technical manual of the American Association of Blood Banks.[11] An average of 465 mL of blood in our experiments was collected into 63 mL of CPDA-1 anticoagulant in Fenwall PL-146 triple-unit bags. PL-732 bags were used for the platelet concentrates. When platelet concentrates were being made, the blood was centrifuged at 1,800 g for three minutes at room temperature in a RC3-B centrifuge with a horizontal H-6000A rotor (Sorvall Instruments, Wilmington, Del), and the supernatant platelet-rich plasma (PRP) was squeezed off by a plasma expressor (Fenwall Laboratories, Deerfield, Ill). The PRP was then centrifuged at 5,000 g for five minutes at room temperature and the supernatant plasma was expressed off: an average of 157 mL of plasma was removed and 53 mL of plasma left with the platelet concentrate. The supernatant plasma was promptly frozen at −65 °C. Alternatively, the whole blood was centrifuged at 5,000 g for five minutes at room temperature and the plasma was expressed off and promptly frozen. An average of 244 mL of plasma was removed with five donors; therefore, about 70 mL of plasma plus anticoagulant were left with the cells. Samples for platelet counts (Thrombocounter, Coulter, Hialeah, Fla) were obtained from the plasma bags before freezing. Because of the greater volume, cryoprecipitate is prepared in our blood bank only from the plasma that had been separated directly from whole blood. The plasma was frozen at −65 °C and then placed at 4 °C to thaw overnight. It was centrifuged at 5,000 g for eight minutes at 4 °C and the supernatant "cryo-poor plasma" expressed off, leaving an average of 13 mL of plasma with the precipitate to refreeze at −65 °C. Whole blood samples were obtained directly from the phlebotomy tubing after the completion of the donation, anticoagulated with 5 mmol/L EDTA, 1 μg/mL prostaglandin E_1, and 0.1 mol/L dibutyryl cyclic adenosine monophosphate, and centrifuged at 12,000 g for ten minutes to obtain plasma for the assay of platelet membrane microparticles.[10]

Platelet membrane microparticles were measured as previously described,[10] using the radioiodinated mouse monoclonal antibody, Tab,[12,13] against glycoprotein (GP) IIb. Plasma samples (0.5 mL) were incubated with 0.5 μg of ^{125}I-Tab for 30 minutes at room temperature. Control samples, subtracted from the plasma samples, contained 0.5 μg of ^{125}I-Tab in buffer. After incubation, the samples were diluted to 7.2 mL with Tyrode's buffer containing 5 mmol/L EDTA and 0.35% bovine serum albumin and centrifuged at 67,000 g at 4 °C for 60 minutes. The buffer was aspirated and the invisible pellet was washed once with 7.2 mL of buffer at 67,000 g for 20 minutes. Then the cpm remaining in the pellet were measured and expressed as molecules of GP IIb per milliliter of plasma, assuming

that one molecule of Tab binds to one molecule of GP IIb. Because the membrane glycoprotein composition of platelet microparticles in plasma is similar to platelets,[10] the measurement of a single membrane glycoprotein, GP IIb, should provide a reasonable estimate of plasma microparticle concentration.

RESULTS

Significant numbers of platelets were present in the plasma used for fresh frozen plasma and to prepare cryoprecipitate. Plasma prepared from PRP contained more platelets than plasma prepared by a single centrifugation of whole blood (33,420 ± 5,615 (SD, n = 5) *v* 13,796 ± 5,204 (n = 5) platelets per microliter, $P < .001$). The centrifugation force is the same for both preparations and sufficient to sediment all platelets.[9] More platelets may be present in the plasma separated from the platelet concentrates because less plasma is left with the platelet pellet than is left above the platelet–white cell layer when the whole blood is separated by the single fast centrifugation. Also, the presence of red cells may affect platelet sedimentation. After frozen storage, as for clinical use, intact platelets were lysed and platelet membrane microparticles were present in the plasma proportional to the original platelet content (Fig 1). The correlation was significant ($r = .89$, $P < .001$). Therefore, the microparticle concentration in fresh frozen plasma prepared from PRP was greater than in fresh frozen plasma prepared directly from whole blood (Table 1). The microparticle concentrations of the donors' original plasmas, obtained by a method to prevent any platelet contamination or activation, were all normal (normal values = 1.95 ± 1.37 (SD) × 10^{10} molecules of GP IIb per milliliter plasma, n = 21, ref 10) and therefore were a negligible contribution to these blood bank plasma samples. The platelet membrane microparticles were significantly concentrated within the cryoprecipitate. In these five samples, the microparticle concentration of cryoprecipitate was 29-fold that of the cryosupernatant plasma, with a range of 20- to 34-fold. The cryoprecipitate contained only 5% of the volume of the original plasma but 48% of the total microparticles. The microparticle concentration was 265-fold that of the donors' original plasma. Using an assumption that the platelet content of GP IIb equals 72,358 molecules per cell (the value we measured by ^{125}I-Tab binding to intact platelets after thrombin-induced secretion, assuming that platelets have no intracellular pool of GP IIb[11]), ten bags of cryoprecipitate would contain an amount of platelet membrane GP IIb equivalent to about 4 × 10^9 platelets, or about 20 mL of blood.

Table 1. Platelet Membrane Microparticles in Fresh Frozen Plasma and the Cryoprecipitate and Cryosupernatant Fractions of Plasma

Preparation	Platelet Microparticles (Molecules GP IIb per mL × 10^{-10})	Volume (mL)
Original donor plasma	0.9 ± 0.5	
Fresh frozen plasma prepared from PRP	100 ± 47	157
Fresh frozen plasma prepared from whole blood	25 ± 5	244
A. Cryoprecipitate	228 ± 30	13
B. Cryosupernate (cryo-poor plasma)	8 ± 2	224

The data are the mean values ± 1 SD for ten samples of cell-free plasma obtained directly from the donors, 13 samples from fresh frozen plasma bags obtained from platelet-rich plasma (PRP) during the preparation of platelet concentrates, and five samples from fresh frozen plasma bags prepared directly from whole blood. The concentration of platelet membrane microparticles was greater in the plasma prepared from PRP than in plasma prepared from whole blood ($P < .005$). The five plasma bags prepared from whole blood were subsequently fractionated into cryoprecipitate and the supernatant "cryo-poor plasma" components, with a significant concentration of platelet membrane microparticles in the cryoprecipitate fraction compared with the whole plasma ($P < .001$). Platelet membrane microparticles were measured using ^{125}I-Tab, a mouse monoclonal antibody to glycoprotein (GP) IIb.

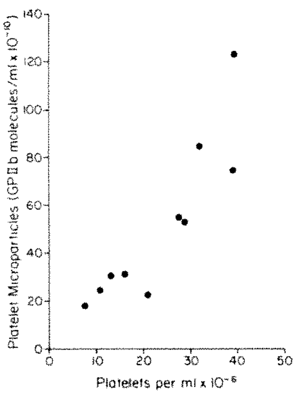

Fig 1. Platelet membrane microparticles in fresh frozen plasma. The number of residual platelets in the fresh plasma immediately after separation from whole blood or from PRP was proportional to the concentration of membrane microparticles present after freezing and thawing (correlation coefficient, $r = .89$, $P < .001$). The data are from five bags obtained from centrifugation of whole blood and five bags obtained from centrifugation of PRP during the preparation of platelet concentrates.

DISCUSSION

Plasma separated to prepare the standard blood bank products, fresh frozen plasma and cryoprecipitate, contained a significant number of platelets. When platelet concentrates were prepared, the resulting supernatant plasma contained more platelets than if the plasma was harvested directly from the whole blood. Platelet counts as high as 39,000 per microliter were observed. Platelet contamination of bank plasma products may have clinically relevant effects, such as cleavage of von Willebrand factor by the platelet calcium-activated protease with loss of the largest multimers.[14] Proteolytic alteration of fibrinogen and fibronectin due to platelet protease activity may also occur.[15,16]

The concentration of platelet membrane microparticles in fresh frozen plasma after thawing was proportional to the number of platelets originally present, and these microparticles were highly concentrated by cryoprecipitation. This process concentrates the large contact-promoting proteins that interact with the platelet surface,[17] fibrinogen, fibronectin, and von Willebrand factor, as well as factor VIII and other proteins,[16,18] and platelet membrane microparticles may be concentrated by an interaction with these proteins. We have found that platelet microparticles in plasma contain the membrane GP Ib and GP IIb–IIIa that can interact with these proteins.[10] The ability of platelet microparticles to bind to fibrinogen, fibronectin, or von Willebrand factor may be enhanced by cryoprecipitation, similar to the enhanced ability of platelets to interact with fibrinogen and von Willebrand factor that are bound onto a solid support.[19-21] Red cell fragments may also be concentrated in cryoprecipitate, as the cryoprecipitate from $Rh(D)^+$ donors can immunize $Rh(D)^-$ patients.[22]

A hemostatic function for platelet microparticles remains speculative. The amount of microparticles in ten to 16 bags of cryoprecipitate[1,2] is only equivalent to the platelets in about 20 to 30 mL of blood, but the dispersion of the platelets' contact-promoting membrane glycoproteins into small particles may amplify their effectiveness. An analogous phenomenon is the shedding into media by tissue culture cells of membrane microparticles, termed adherons, that promote both cell adhesion to the substratum and cell–cell aggregation.[23] This function can be blocked by a monoclonal antibody to a 170,000-molecular weight membrane protein shared by the intact cells and adherons.[24] The mechanism of adheron function is unknown, but it is assumed to relate to the concentration of cell adhesion molecules in small particles that can facilitate contact between cells and surfaces.[23] A similar property may be postulated for platelet membrane microparticles.

Because our data were obtained by standard procedures[11] in a general hospital blood bank, these observations should be relevant to plasma components prepared for routine clinical use. Therefore, the presence of platelet membrane microparticles must be considered in interpreting the effects of transfused plasma products.

CONCISE REPORT

Spurious Detection of Terminal Deoxynucleotidyl Transferase in Phytohemagglutinin-Stimulated Lymphocytes

By J.A. Fletcher, R. Bell, M. Koekebakker, A.A. Dowers, R.P. McCaffrey, and R.D. Barr

Expression of terminal transferase (TdT) is believed to be restricted to primitive lymphoid cells; recently, however, indirect immunofluorescent (IF) assays have been used to demonstrate the apparent presence of TdT in phytohemagglutinin (PHA)-stimulated peripheral blood lymphocytes and in various nonlymphoid malignancies. Using an IF assay, we found that a heteroantiserum to TdT reacted with cultured and PHA-stimulated human peripheral blood mononuclear cells, but we were unable to confirm the presence of TdT in these cells using immunoblotting and biochemical assays. We conclude that the IF results are spurious and most likely represent recognition by the heteroantiserum of inducible protein(s) other than TdT.
© 1986 by Grune & Stratton, Inc.

TERMINAL deoxynucleotidyl transferase (TdT) is a unique template-independent DNA polymerase that is expressed, in the normal host, only in primitive T and B lymphoid cells. The biochemical properties and limited anatomic expression of TdT suggest that the enzyme may be responsible for genomic alterations which contribute to the generation of somatic immunologic diversity,[1] but this cellular role remains speculative. Nevertheless, TdT assays have become clinically important over the past decade; elevated levels of TdT in acute leukemia, non-Hodgkin's lymphoma, and CML-blast crisis specimens, indicate that the disease is biochemically lymphoblastic in nature and that there is a high likelihood of response to conventional vincristine-prednisone-based chemotherapy regimens.[2,3]

The primitive T and B lymphocytes, which normally express TdT, are restricted to the thymic and bone marrow compartments; there are very few circulating TdT-positive cells.[4,5] However, several recent reports describe the identification of TdT-positive cells, by indirect immunofluorescent (IF) methods, in peripheral blood mononuclear cells following viral stimulation,[6] in patients with AIDS,[7] culture in a diffusion chamber,[8] and phytohemagglutinin (PHA) stimulation.[9] Because biochemical assays have not revealed enzymatic TdT activity in PHA-stimulated human mononuclear cells,[10,11] it may be that the IF assays in these instances have detected a TdT-like protein that is biologically inactive ("true-positive" result) or a non-TdT protein that cross-reacts with components of some anti-TdT reagents ("false-positive" result). To characterize the questionable presence of TdT in cultured and PHA-stimulated human mononuclear leukocytes better, we studied these cells with an immunoblot detection system that is sensitive and specific for TdT.

MATERIALS AND METHODS

Cells. Mononuclear cells, obtained from a healthy volunteer (subject A), were isolated by density-gradient separation of 200 mL of heparinized blood on Ficoll-Hypaque. These cells were analyzed for TdT using the IF and immunoblot assays at the time of cell separation (day 0) and after 5 days of culture in the presence (day 5 + PHA) and absence (day 5 − PHA) of PHA. Mononuclear cell preparations were obtained, in identical fashion, from four other healthy volunteers (subjects B, C, D, and E) manipulated as above, and then pooled to allow sufficient cell numbers for biochemical assays of TdT activity; these samples were also studied with the immunoblot assay. Leukemic cells and calf thymocytes were harvested and processed as described previously.[12]

Immunofluorescent assay. IF assay was performed as described previously.[13] Unfixed cytocentrifuge preparations ($\sim 5 \times 10^5$ cells per slide) were incubated sequentially with rabbit anti-calf TdT serum (P.L. Biochemicals, Milwaukee) and FITC-IgG goat anti-rabbit IgG (Cappel Laboratories, Cochranville, Penn). Results were expressed as percentage of total cells showing a granular pattern of fluorescence (Fig 1A).

Biochemical assay. The biochemical assays were performed as described previously[14] using phosphocellulose column fractions prepared from the lysates of 0.4 to 1×10^8 cells. The reaction mixtures contained ^{3}HdGTP and oligo(dA)$_{50}$, and calf thymocytes served as the positive control.

Immunoblot Assay. Cells (1×10^7) were lysed by sonication at 4 °C in 0.5 mL of RIPA buffer (0.02 mol/L of Tris, pH 7.5; 0.1 mol/L of NaCl; 200 KIU/mL of Aprotinin; 1 mmol/L of EDTA; 1 mmol/L phenylmethylsulfonyl fluoride (PMSF) (Sigma, St Louis); 0.5% Triton-X). Lysate protein concentrations were determined using the BioRad protein assay (BioRad, Richmond, Calif), and 40 µg of each lysate was dissolved in Laemmli sample buffer and subjected to Western blotting following standard procedures.[15] The western blots were incubated sequentially with: (a) 6% goat serum; 0.05% Tween-Tris-buffered saline at 30 °C for 30 minutes; (b) 1:60 dilution of partially purified rabbit anti-calf TdT (P.L. Biochemicals) in 2% goat serum; 0.05% Tween-Tris-buffered saline at 4 °C for 24 hours; and (c) 1:1,000 dilution of peroxidase linked goat anti-rabbit IgG (Cappel Laboratories) at 30 °C for 1 hour. The peroxidase activity was then visualized using 4-chloro-1-naphthol and H_2O_2.

RESULTS

The immunoblot protocol was carried out initially on a series of positive controls that included human thymocytes and nine enzymatically TdT-"positive" acute leukemia samples; the negative controls were five acute leukemia samples that were known to lack enzymatic TdT activity. The positive controls uniformly showed a band of a mol wt of ~60 kd, which is the weight of nonproteolyzed human TdT,[16,17]

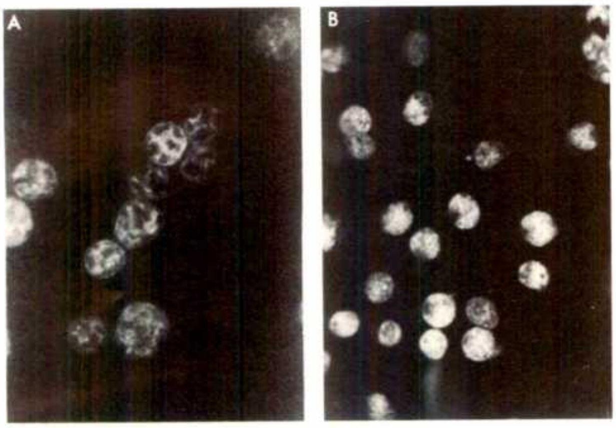

Fig 1. Immunofluorescent staining for TdT. (A) Acute lymphoblastic leukemia cells (biochemically TdT$^+$). (B) Peripheral blood mononuclear cells that have been cultured for 5 days in the presence of PHA.

whereas the negative controls showed no such band (Fig 2A). In mixing studies of the TdT-positive and TdT-negative specimens shown in Fig 2A, the TdT immunoblot assay was able to detect a 1% population of TdT-positive cells (data not shown).

The peripheral blood mononuclear cells obtained from subject A were negative for TdT by immunofluorescence at day 0; after 5 days of culture with and without PHA, however, these cells were, respectively, 72% and 61% TdT-positive by IF (Fig 1B); none of these samples was found to have TdT by the immunoblotting protocol (Fig 2B). The parallel experiment, using pooled mononuclear cells from subjects B, C, D, and E, revealed no elevations (all samples <0.2 U/10^8 cells) of enzymatic TdT activity at day 0, day 5 + PHA, and day 5 − PHA; again, each of these samples was negative for TdT by the immunoblotting method.

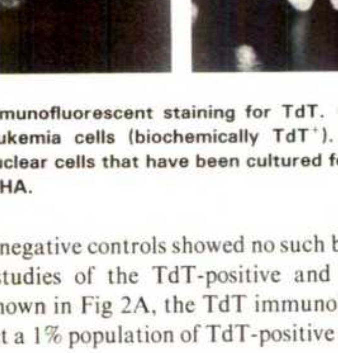

Fig 2. (A) TdT immunoblot of chronic myelogenous leukemia in blast cell crisis (lane 1) and acute myelogenous leukemia (lane 2). Mol wt markers are indicated in kilodaltons. Lane 1 shows a single band at 60 kd, which is the known mol wt of nonproteolyzed human TdT. The CML-BC sample had enzymatic TdT activity, whereas the AML sample lacked enzymatic TdT activity. (B) TdT immunoblots of peripheral blood mononuclear cells at day 0 (lane 1), after 5 days of culture in the absence of PHA (lane 2), and after 5 days of culture in the presence of PHA (lane 3). Also included is an acute lymphoblastic leukemia sample (lane 4) that was known to have enzymatic TdT activity. The ALL sample has a strong band at 60 kd that is not present in any of the peripheral blood mononuclear cell groups. The day 5 + PHA cells show a strong band at ~75 kd that is also faintly present in the day 5 − PHA and ALL cells.

DISCUSSION

In several previous investigations, IF methods have been used to document TdT activity in cultured and PHA-stimulated adult peripheral blood mononuclear cells,[8,9] suggesting that blastic transformation of lymphocytes may be accompanied by TdT expression. Cyclic AMP has been shown, by immunoprecipitation and biochemical assays, to induce TdT expression in lymphocytes, but this induction is restricted to pre-B cells.[18] We have confirmed that cultured and PHA-stimulated adult peripheral blood mononuclear cells show "TdT activity" when examined by an established IF assay; however, these same cells do not show TdT activity when examined by biochemical and immunoblotting techniques.

Although our IF results demonstrate that certain anti-TdT reagents react with cultured and mitogen-stimulated lymphocytes, the absence of enzymatic TdT activity in these cells and the absence of the characteristic 60-kd human TdT band with immunoblotting lead us to believe that the anti-TdT reagent is reacting with inducible proteins other than TdT. These findings also suggest that previous immunofluorescent and immunohistochemical determinations of apparently strong TdT activity in nonmalignant bone marrow and peripheral cells[19,20] and in nonlymphoid malignancy[21] may represent a similar recognition of inducible non-TdT proteins by heterospecific anti-TdT reagents. We were not able to discriminate between reactivity with these non-TdT proteins and with actual TdT based on the morphologic pattern of IF staining.

Several of the day 5 − PHA and day 5 + PHA immunoblots revealed a strong band at a mol wt of ~75 kd; this may represent the protein that is recognized in the IF assays. There are several known T cell antigens in this mol wt region, but the number of proteins synthesized by mitogen-activated lymphocytes is large,[22] and the actual identity of this 75-kd entity is unknown.

The poor specificity of the TdT antiserum used for our IF assays should be partially rectified with the use of affinity-purified reagents. Unfortunately, the available affinity-purified reagents have shown suboptimal sensitivity in IF assays,[13] and it remains to be seen whether monoclonal antibodies to TdT[23,24] will allow increased specificity in IF and immunohistochemical testing without significant loss of sensitivity. In general, either the biochemical or IF TdT assay can appropriately be used to classify acute hematologic malignancies, as both assays have shown good concordance when used to diagnose acute leukemias and lymphomas of the lymphoblastic type.[25] The IF assay, however, has been unreliable in detecting relapse of leukemia or lymphoma.[6,9] Therefore, positive IF results in this context should be confirmed by the immunoblot or other independent assays; this same recommendation applies to the IF detection of TdT in nonhematologic malignancies and in viral or mitogen-stimulated lymphocytes. The finding of TdT induction, when documented by IF alone, should be interpreted with caution.

CONCISE REPORT

Effects of Recombinant GM-CSF on the Blast Cells of Acute Myeloblastic Leukemia

By T. Hoang, N. Nara, G. Wong, S. Clark, M.D. Minden, and E.A. McCulloch

The effects of recombinant granulocyte-macrophage colony-stimulating factor (GM-CSF) were compared to those of media conditioned by the continuous bladder carcinoma line, HTB9 (HTB9-CM), using three criteria. First, both GM-CSF and HTB9-CM stimulated blast colony formation in methylcellulose cultures, patient-to-patient variations were seen in the dose–response curves, and GM-CSF was effective, but less so than HTB9-CM. Second, GM-CSF also enhanced growth of blast progenitors in suspension culture, indicating its capacity to support self-renewal. GM-CSF was as effective as HTB9-CM in the production of adherent cells during the growth of blast cells in suspension, a finding that is interpreted to mean that GM-CSF also supports postdeterministic events in blast differentiation. Finally, colonies growing in the presence of GM-CSF were not phenotypically different than those stimulated by HTB9-CM.

© 1986 by Grune & Stratton, Inc.

A MOLECULAR clone has been isolated for the hematopoietic growth factor, granulocyte-macrophage colony-stimulating factor (GM-CSF)[1]; the factor has been transfected into Chinese hamster ovary (CHO) cells and a line that continuously produces GM-CSF has been obtained.[2] The availability of this recombinant GM-CSF makes it possible to test its effects on various target cells.

GM-CSF was first described as a growth requirement for granulopoietic-macrophage colony formation in culture.[3] It also supported the initial divisions of multipotential and erythropoietic precursor cells, but further differentiation and proliferation of these cells required other growth factors.[4] With recombinant GM-CSF at high concentrations, the requirement for additional stimulator was no longer seen.[5] In this article, we report the effects of recombinant GM-CSF on blast cells from patients with acute myeloblastic leukemia (AML). We find that GM-CSF stimulates both the formation of blast colonies in methylcellulose[6] and the growth of blast progenitors in suspension.[7] In addition, recombinant GM-CSF increases the production of adherent AML blasts, cells that have been shown previously to have some of the phenotypic characteristics of macrophages.[8]

MATERIALS AND METHODS

Cells

With the patients' informed consent, cells were obtained from the peripheral blood of three patients with AML. The sample from patient 1 (French-American-British classification, FAB 4) was obtained at relapse following treatment with high-dose cytosine arabinoside.[9] Patient 2 (FAB 1) was seen at first occurrence and was treated with a combination of Adriamycin, cytosine arabinoside, and thioguanine.[10] Patient 3 (FAB 4) was in relapse following treatment with high-dose cytosine arabinoside.[9]

The suspensions were depleted of T cells by sheep erythrocyte rosetting as described previously.[11] Normal bone marrow cells were obtained from marrow transplant donors; these populations were depleted of adherent cells by overnight incubation in Iscove's medium (GIBCO, Grand Island, NY) with 10% fetal calf serum (FCS, GIBCO). The human bladder carcinoma cell line (HTB9) was obtained from Dr Robert Phillips of this institute; the cells are maintained in α-medium (α-MEM) (GIBCO) supplemented with 4% FCS.

Source of Growth Factors

Conditioned medium from HTB9 and recombinant GM-CSF. HTB9-CM was harvested on day 7, 2 to 3 days after the cells became confluent. The HTB9-CM was sterilized by filtration (Millipore, .22 μ-m) and stored at 4 °C. One batch, selected for its potency as a stimulator of colony formation by AML blasts, was used without purification as a standard in all experiments. Recombinant GM-CSF was obtained from the Genetics Institute, Boston, as unpurified supernatant from GM-CSF-transfected CHO cells. This material contains 1% bovine serum and $>10^5$ U of GM-CSF.

Cell cultures. Recombinant GM-CSF was compared with HTB9-CM in cultures of blast cells from patients with AML and marrow cells from normal donors. The effect of growth factors on blast colony formation was tested by plating cells in 96-microwell plates (Linbro, Flow Lab, McLean, Va) as described previously, in α-MEM supplemented by 10% FCS and 0.8% methylcellulose.[12] Each well contained from 10^3 to 10^4 cells in 100 μL of medium; these cell concentrations were selected to yield a minimum number of colonies in the absence of added factor. The putative stimulators to be tested were added to the wells in dilutions ranging from 10^{-7} to 10^{-2}. The cultures were incubated for 5 to 7 days in a moist atmosphere containing 5% CO_2, and colonies were enumerated using an inverted microscope.

Blast cells were cultured in suspension in 35-mm Petri dishes (Lux) in α-MEM and 20% FCS as described previously.[7] Cells from patient 1 can be maintained for long periods in suspension; their exponential growth for 224 days has been described[13] and still continues; growth remains dependent on the addition of HTB9-CM to the cultures. Growth factors were added at the same range of dilution given above. After 7 days, the cells were harvested and plated in methylcellulose with an optimal concentration of HTB9-

CM (10%). The recovery of clonogenic cells was obtained by multiplying the plating efficiency in methylcellulose by the number of cells harvested from the suspension.

The assay for adherent cells was a minor modification of that described by Langley and colleagues[8] in which blast cells were cultured in suspension in Lux tissue culture microwells for 7 days. The nonadherent cells were then removed, and the residual adherent cells were counted using an inverted microscope. Based on cell sources, the kinetics of development of the adherence property, and the cell phenotypes, we concluded that the adherent cells belonged to the blast population.[8]

Normal nonadherent bone marrow cells were plated at a concentration of 5 × 10^4 in 35-mm Petri dishes in Iscove's medium supplemented with 10% FCS, deionized bovine serum albumin (BSA) (Hoechst, Calbiochem-Behring, La Jolla, Calif, electrophoretically pure, 10 mg/mL), iron-saturated human transferrin (Hoechst, 360 mg/mL), α-thioglycerol (10^{-4}mol/L), purified homogeneous erythropoietin (obtained from the Terry Fox Laboratory, University of British Columbia, 1 U/mL), and methylcellulose. As in the previous assays, various concentrations of growth factors were added; colonies were assessed both for number and morphology with an inverted microscope after 7 and 14 days of incubation. The concentration required for half-maximal stimulation of granulocyte and macrophage colonies was defined as 1 U of activity.[12] The batch of recombinant GM-CSF used for the present study contained 1.2 × 10^5 U/mL. At plateau concentration, it stimulated the same number of granulocyte and macrophage colonies as HTB9-CM. In the presence of erythropoietin, it also supported the growth of multipotential and large erythroid colonies.

Monoclonal antibodies. Phenotypes of blast cells were determined before and after culture, using indirect immunofluorescence, as described previously.[14] The antibodies used were My-1,[15] My-7, and My-9[16,17] that recognize granulopoiesis-associated antigens, and MO1[18] that binds markers of both granulopoietic cells and macrophages.

RESULTS

Titrations

Titration of GM-CSF on blast colony formation in methylcellulose, growth of clonogenic blast progenitors in suspension, and the generation of adherent blast cells are shown in Fig 1. Panel A depicts the increase in blast colonies observed with increasing concentration of GM-CSF. Data from three patients are shown. For patient 1, the cells were obtained after frozen cells had been maintained in suspension culture for 3 weeks. Cells from the other patients were tested when obtained or from cyropreserved samples. Patient-to-patient variation is evident. However, in each instance, the dose–response curve extended over several tenfold dilution steps. The maximum values for colony formation obtained with a standard HTB9-CM preparation are given in the legend to Fig 1. In no instance was this value obtained with GM-CSF, although no obvious differences in colony size were noted. Indeed, for patient 1, only 19% of the colonies stimulated by HTB9-CM were seen with a concentration of GM-CSF much greater than that required for maximum stimulation of granulopoietic colonies (8,000 U/mL).

Panel B shows the effects of increasing GM-CSF concentration on recovery of clonogenic blasts after 7 days in suspension culture. Again, a dose-related increase was seen, although the form of the dose–response curve was different for the two samples depicted in panel B of Fig 1. Cells from patient 1 were tested after almost 1 year in continuous suspension culture; their response to recombinant GM-CSF was similar to that seen with HTB9-CM (see legend to Fig 1). For patient 2, GM-CSF was less effective than HTB9-CM.

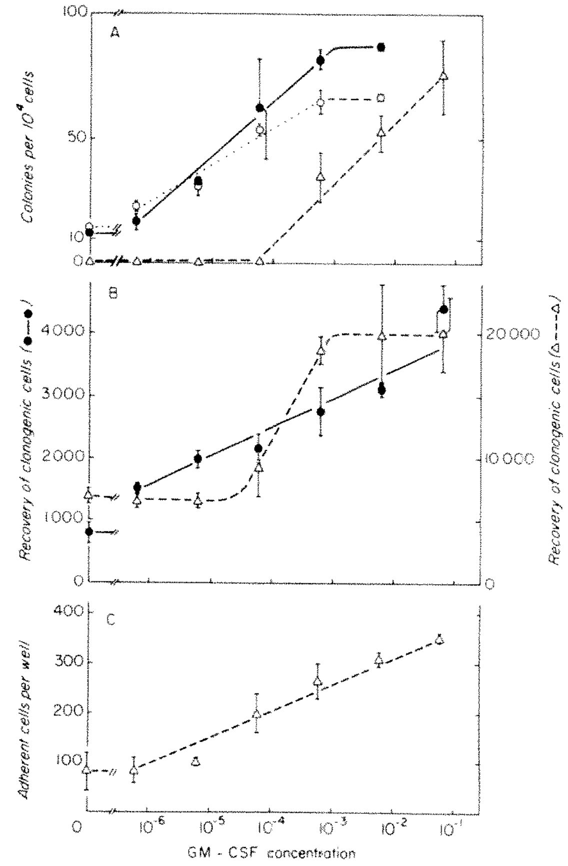

Fig 1. Recombinant granulocyte-macrophage colony-stimulating factor (GM-CSF) dose–response curve. (A) In methylcellulose cultures of blast progenitors. Maximum stimulation by HTB9-CM was: 430 ± 20 (AML 1, Δ---Δ), 155 ± 7 (AML 2, ●—●), 148 ± 6 (AML 3, O---O). (B) In suspension cultures. Recovery in clonogenic cells with HTB9-CM was: 47,000 ± 3,400 (AML 1) and 3,860 ± 290 (AML 2). Symbols as in A. (C) In the generation of adherent cells. The input cell number was 10^4 per well. Maximum number of adherent cells per well with HTB9-CM was: 405 ± 27 (AML 1). Symbols as in A.

The generation of adherent blast cells in suspension cultures is shown in panel C as a function of GM-CSF concentration. The cells were from patient 1, tested after many months in suspension culture. Again a dose response was obtained, reaching almost the same value as that seen with HTB9-CM, even though the cells were those that responded poorly to GM-CSF in the assays based on proliferation (patient 1). The same increase in adherent cells in the presence of GM-CSF was seen with samples 2 and 3 (data not shown).

Phenotypes

Using monoclonal antibodies directed against granulopoietic and monocytic differentiation antigens, the phenotypes of blast cells were determined before plating and from blast colonies. Results of an experiment representative of four experiments are given in Table 1. In agreement with past findings,[19] myelopoietic markers increased during colony formation. Evidence of granulopoietic maturation was not seen. No difference was observed between colonies grown in the presence of GM-CSF as compared with those grown in the presence of HTB9-CM.

Table 1. Surface Markers on Colony Cells

	MO1 (%)	My-1 (%)	My-7 (%)	My-9 (%)
Before culture	25	12	23	74
After culture				
Control	30	44	79	63
GM-CSF	15	54	36	78
HTB9-CM	37	76	45	30

Results expressed as percentage of positive cells (AML 1).

DISCUSSION

The major finding of this article is that recombinant GM-CSF is able to stimulate blast colony formation in methylcellulose cultures[6] and the growth of blast progenitors in suspension. The latter assay is considered to reflect the renewal potential of blast stem cells;[7] furthermore, colonies grown in methylcellulose cultures in the presence of recombinant GM-CSF were replated successfully (data not shown), confirming the ability of GM-CSF to support self-renewal.[20] Finally, the capacity of GM-CSF to increase the number of adherent cells is evidence for its support for differentiation-like events, since adherent blast cells usually show increased expression markers often associated with macrophages as well as those characteristic of the blast population.[8]

Recently, we reported[13] that supernatants from cultures of the continuous cell line HTB9 (HTB9-CM) were effective stimulators of blast colony formation. On the basis of partial separation of Sephadex G100, we suggested that the active growth factor for blast colony formation (leukemic blast growth factor or LBGF) might not be identical to GM-CSF. The present study does not contradict that suggestion, since GM-CSF was usually a much less powerful stimulator than HTB9-CM. Rather, the data is now consistent with the possibility that colony formation or growth of blast progenitors may require more than one factor, working singly or in combination.

Our data confirm the findings of others that GM-CSF will stimulate multilineage colonies as well as colonies containing only granulocytes and macrophages,[4,5] a finding that prevents the use of GM-CSF response for lineage definition. In the context of this report, the finding that GM-CSF is active on AML blast progenitors is not evidence that these cells belong exclusively to a lineage related to granulopoietic or macrophage differentiation. In the experiment reported here, it is unlikely that adherent cells not from the leukemic clone were detected, since the blasts had been maintained for >1 year with repeated subcultures.

Finally, our results may have practical significance. GM-CSF has been considered as a putative therapeutic agent. Indeed, preclinical trials have been reported.[21] The ability of GM-CSF to stimulate the growth of blast progenitors suggests that it may be contraindicated in the treatment of any condition related to AML or capable of progression to that disease.

CONCISE REPORT

Fragment D-Dimer Levels: An Objective Marker of Vaso-occlusive Crisis and Other Complications of Sickle Cell Disease

By Dana V. Devine, Thomas R. Kinney, Patricia F. Thomas, Wendell F. Rosse and Charles S. Greenberg

Although abnormalities in coagulation tests have been reported during vaso-occlusive crises in patients with sickle cell disease, objective, readily performed laboratory tests that document the occurrence of this complication have not been available. We examined the relationship between fibrin D-dimer levels and the occurrence of complications in patients with sickle cell disease, using a commercially available latex bead agglutination assay. The patients were either asymptomatic, hospitalized for vaso-occlusive crisis, or had other complications of sickle cell disease including leg ulcers, chronic cholecystitis, aseptic necrosis, joint pain and infection. Fifty-seven percent of 187 samples on 96 patients had elevated levels of fibrin D-dimer. Ninety percent of 75 samples from asymptomatic patients were negative for fibrin D-dimer (<1 μg/ml) but 97% of 29 samples from patients with vaso-occlusive crisis and 85% of 83 samples from patients with other complications of sickle cell disease were positive. In serial studies, worsening or amelioration in clinical complications were reflected in increasing or decreasing levels of fibrin D-dimer, respectively. The molecular species of fibrin identified by the latex agglutination test was shown to be fragment D-dimer by successive immunoprecipitation and protein blot analysis. We conclude that the complications of sickle cell disease, including vaso-occlusive crisis, result in the production of fibrin D-dimer, and its detection may be used as a marker for the presence of the complication.
© 1986 by Grune & Stratton, Inc.

THE ROLE OF blood coagulation in the pathogenesis of sickle cell disease is poorly understood. It is, however, known that patients in vaso-occlusive crisis have evidence of intravascular coagulation since fibrinopeptide A levels are elevated in sickle cell crisis.[1] In addition, the activation of coagulation factors may have a profound effect on blood viscosity in sickle cell patients.[2] Sickled erythrocytes adhere to vascular endothelial cells[3,4] and this adherence is enhanced by autologous plasma proteins.[5,6] Therefore, the occlusion of the microvasculature by sickled erythrocytes may be enhanced by interactions with coagulation factors. Sickled erythrocytes[7] or purified spicules from such erythrocytes[8] accelerate blood clotting in vitro. Whether the activation of the coagulation pathway is contributory to vaso-occlusive crisis is unknown. In addition to episodes of painful crisis, many adult patients with sickle cell disease suffer from more chronic complications of the disease, including leg ulcers, aseptic necrosis of bone, and chronic cholecystitis.

To determine if laboratory measurements of fibrinolytic activity are related to the clinical status of the patient and might therefore provide an objective measurement of disease activity, we used a newly available, simple, and rapid latex bead agglutination assay (Dimertest) which is specific for the fragment D-dimer domain in Factor XIII$_a$-crosslinked fibrin. The monoclonal antibody used in the Dimertest, DD-3B6, measures both fragment D-dimer and fragment D-dimer/fragment E complex in plasma.[9] Fragment D-dimer/fragment E complex is a terminal breakdown product of crosslinked fibrin; therefore its presence in plasma is evidence of fibrinolysis. For the purpose of discussion, fibrin D-dimer will refer to the fragment D-dimer domain in all molecular species of crosslinked fibrin and fibrin degradation products. Fibrin D-dimer levels are elevated in fibrinolytic states including disseminated intravascular coagulation, pulmonary embolism, and deep venous thrombosis.[10] We have used this assay to show that there is a strong relationship between fibrin D-dimer levels and disease activity in patients with sickle cell disease.

MATERIALS AND METHODS

Patient samples. EDTA plasma was obtained from blood samples drawn for routine blood count or hemoglobin electrophoresis. Ninety-six patients (68 adults and 28 children) are reported in the present study. Of these, 79 are homozygous for hemoglobin S (Hb SS), ten have Hb SC disease, five have Hb S β^+ thalassemia and one each has Hb SD disease and Hb S β^0 thalassemia. All of these patients have some history of one or more of the complications of sickle cell disease, including vaso-occlusive crisis, leg ulcers, infections (osteomyelitis, pneumonia, viral illness), chronic cholecystitis, aseptic necrosis and bone marrow infarction.

Measurement of fibrin D-dimer levels. To measure the levels of fibrin D dimer in EDTA plasma samples we used the Dimertest latex agglutination assay (American Diagnostica, Greenwich, Conn) according to the manufacturer's recommendations. The minimum amount of fibrin D-dimer detected by the assay is 1 μg/ml.[11] All assays were performed by the same person, who was unaware of the clinical status of the patient. Statistical analysis of the relationship between disease activity and Dimertest results was performed using the G-test of independence.[12]

Assessment of patient clinical status. The patient's clinical status at the time the fibrin D-dimer assays were performed was assessed by history and physical examination. The evaluation was made without knowledge of the assay results. Patients were asymptomatic, were hospitalized in vaso-occlusive crisis, or were having

other complications of sickle cell disease. Vaso-occlusive crisis was defined as multiple sites of skeletal or other pain lasting at least 12 hours. The other complications of sickle cell disease in these patients included leg ulcers, aseptic necrosis of bone, joint pain, stroke, cholecystitis and infection (pneumonia, osteomyelitis, viral infection).

Biochemical analysis of fragment D-dimer. In order to determine which molecular species of fibrin were recognized by the Dimertest, we analyzed fibrin-related antigens present in EDTA serum. EDTA plasma samples which contained measurable fibrin D-dimer were clotted with thrombin (gift of Dr John W. Fenton II, New York State Department of Health, Albany, NY) and the clot was removed. Fibrinogen-related antigens were immunoprecipitated from serum using rabbit antihuman fibrinogen and Cowan I strain *Staphylococcus aureus* cells (both from Calbiochem-Behring, San Diego) under conditions previously determined to remove all fibrinogen-related antigens. As a control, immunoprecipitations were performed using nonimmune rabbit serum. The precipitates were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) under nonreducing conditions and transferred onto nitrocellulose paper by the method of Towbin et al.[13] The blot was probed first with monoclonal antibody DD-3B6 obtained from the enzyme-linked immunosorbent assay (ELISA) form of the Dimertest, and second with ^{125}I-labeled F(ab')$_2$ sheep antimouse immunoglobulin (Amersham, Arlington Heights, Ill). Samples of purified fragment D[14] and fragment D-dimer[15] were electrophoresed in the same gels to serve as internal standards. The blot was then dried and autoradiographed.

RESULTS

Of the 187 samples of EDTA plasma from 96 sickle cell patients tested, 57% had elevated levels of fibrin D-dimer. Normal plasma samples from healthy donors were always negative. When the fibrin D-dimer levels were related to the clinical status of the patients (Fig 1), there was a significant association between disease activity and the presence of fibrin D-dimer ($G = 132.068$, $P < 0.001$). Of 75 samples from 38 asymptomatic patients, only 10% contained measurable levels of fibrin D-dimer. Samples from 14 patients in vaso-occlusive crisis were Dimertest-positive 97% of the time. Samples from six of the patients were taken when the patients were asymptomatic; all of these were Dimertest negative. Among all samples from patients in vaso-occlusive crisis, only one was negative and this patient's diagnosis was not supported by physical findings. In the course of the same hospital admission, this patient experienced chest pain accompanied by a fall in pO_2. A plasma sample drawn 24 hours later contained measurable fibrin D-dimer.

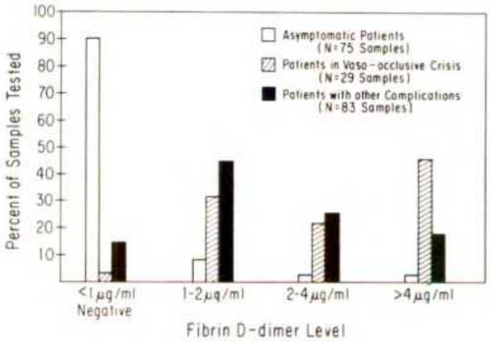

Fig 1. The fibrin D-dimer levels in patients with sickle cell disease grouped according to clinical status. Fibrin D-dimer levels were measured using a latex bead agglutination assay described in Materials and Methods. There is a statistically significant association between elevated D-dimer levels and complications of sickle cell disease ($p < 0.001$).

Eighty-six percent of samples from symptomatic patients not hospitalized for management of vaso-occlusive crisis had elevated levels of fibrin D-dimer. Serial samples were obtained from ten patients in this group who experienced changes in their clinical status other than hospitalization for vaso-occlusive crisis. In all cases, those who developed complications developed measurable levels of fibrin D-dimer while those whose complications resolved became negative in this assay.

There were 14 of the 96 patients (15%) in whom fibrin D-dimer levels did not correlate with clinical symptoms. In eight asymptomatic patients (three adults and five children), fibrin D-dimer levels were elevated while in six symptomatic patients fibrin D-dimer levels were normal. In the latter group, two patients had leg ulcers and four had subjective complaints of pain.

The amount of fibrin D-dimer measured by the agglutination assay was the same in EDTA plasma or serum prepared

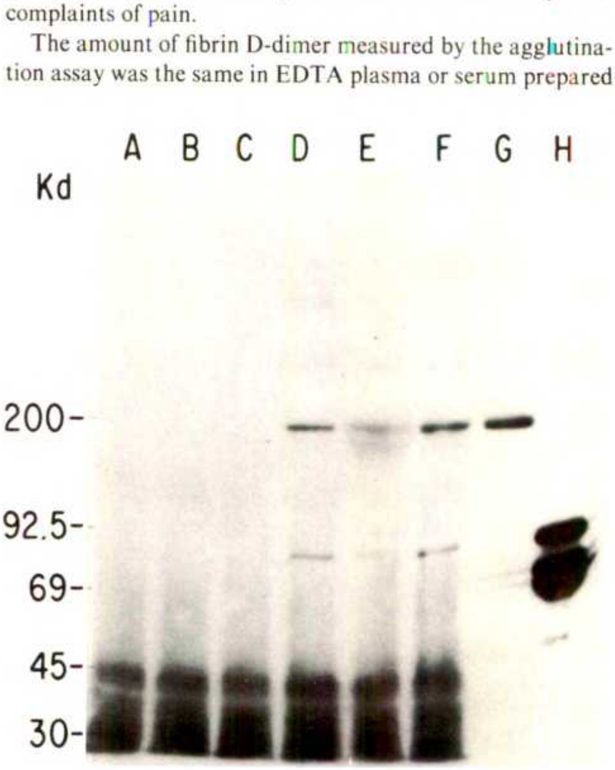

Fig 2. Immunoprecipitation/protein blot analysis of fibrin-related antigens recognized by monoclonal antibody DD-3B6 in plasma samples from sickle cell patients with elevated fibrin D-dimer levels. Control precipitations using nonimmune rabbit serum are found in Lane A (normal donor plasma) and Lane B (Dimertest-positive plasma from a sickle cell patient). As described in the text, fibrin-related antigens were precipitated from serum prepared using thrombin-clotted EDTA plasma samples from a normal donor (Lane C), or Dimertest-positive samples from a sickle cell patient in vaso-occlusive crisis (Lane D) or patients with other complications of sickle cell disease (Lanes E and F). Purified fragment D-dimer and fragment D were electrophoresed in Lanes G and H, respectively. The protein blot was probed with DD-3B6, then radiolabeled F(ab')$_2$ sheep antimouse immunoglobulin.

from thrombin-treated EDTA plasma. Immunoprecipitation/protein blot analysis of the fibrinogen-related antigens in these sera demonstrated that the monoclonal antibody DD-3B6 recognizes primarily fragment D-dimer in addition to some fragment D1 and higher molecular weight fibrin fragments in the Dimertest-positive samples from patients with either vaso-occlusive crisis or other complications of sickle cell disease (Fig 2).

DISCUSSION

There are no practical and readily available laboratory measurements currently in use which correlate with disease state in sickle cell disease. However, there are reports of abnormal coagulation activity in patients with sickle cell disease. Richardson et al[2] found elevated levels of factor VIII:C, factor VIIIR:Ag, and antithrombin III in the plasma of eight patients in steady state which rose higher when the patients were in vaso-occlusive crisis. The onset of vaso-occlusive crisis is also accompanied by an increase in plasma high-molecular-weight fibrinogen complexes (HMWFC).[16] Fibrinopeptide A (FPA) levels have been used to measure coagulation activity in patients in vaso-occlusive crisis. Leichtman and Brewer[1] demonstrated that the FPA level in pain-free patients is generally within normal range but increases with the onset of painful crisis. However, the measurement of both HMWFC and FPA is technically cumbersome and the latter assay is highly susceptible to false positive results due to traumatic venipuncture. Only one of these studies[16] measured coagulation factors in patients with the more chronic complications of sickle cell disease. The single patient with leg ulcers reported showed normal levels of HMWFC.

The measurement of fibrin D-dimer with the latex bead agglutination assay showed significant correlation with disease activity in sickle cell disease. Asymptomatic patients were fibrin D-dimer negative, while patients in vaso-occlusive crisis or patients with other complications of sickle cell disease were positive. Fibrin D-dimer levels may be elevated in conditions other than sickle cell disease. We have found that 28% of 150 random samples from hospitalized patients had measurable levels of fibrin D-dimer.[11] Most of these patients either had diseases associated with an increase in fibrinolytic activity or had recently undergone surgery.

Protein blot analysis of the species of fibrin recognized by the monoclonal antibody in plasma from sickle cell patients demonstrated that while the fragment D-dimer was the predominant species, presumably representing circulating fragment D-dimer/fragment E complexes, some fragment D1 and higher molecular weight forms of fibrin were detected in the blot. The latter may represent fragment DY or fragment Y dimers. Although DD-3B6 recognized fragment D in protein blot analysis, this fragment in fluid phase does not cause agglutination in the Dimertest assay.

The data reported here give no indication of the role abnormal coagulation activation plays in sickle cell disease. It is unclear whether abnormal fibrinolytic activity precipitates the onset of vaso-occlusive events, or is a result of vascular occlusion or vascular injury. However, the close correlation of fibrin D-dimer levels and the patient's clinical condition may provide useful information in the management of patients with sickle cell disease and in the evaluation of therapeutic regimens.

ACKNOWLEDGMENT

We thank Martha Sawtschenko and Mary Whorton for their help in sample collection.

CORRESPONDENCE

t(1;3)(p36;q21) IN ACUTE NONLYMPHOCYTIC LEUKEMIA: A NEW CLINICOPATHOLOGIC ASSOCIATION

To the Editor:

We agree that t(1;3)(p36;q21) recently reported by Bloomfield et al[1] may prove to be a new cytogenetic-clinicopathologic association in acute nonlymphocytic leukemia (ANLL). This observation should, however, be handled with caution for the following reasons. Weakness and moderately severe anemia do not make up a particularly strong clinical association in a setting such as ANLL, in comparison to associations such as t(8;21) with long-term survival,[2] t(15;17) with intravascular coagulation,[3] and del(16) or inv(16) with high incidence of central nervous system relapse.[4] Furthermore, hematologic findings, such as marrow dyserythropoiesis, should not be considered as a specific hematologic association in view of the fact that ANLL in the adult frequently involves a stem cell that is multipotent for erythrocytes, granulocytes, and platelets[5] and can thus result in variable degrees of dyshematopoiesis.[6]

The most striking finding reported with t(1;3) is dysmegakaryocytopoiesis characterized by normal to increased hypolobulated megakaryocytes. As stated, two other rearrangements of band 3q21 have previously been associated with such findings.[7,8] Furthermore, three other subsets of patients with ANLL have been identified with a similar dysmegakaryocytopoiesis: patients with FAB M4-ANLL,[6] with FAB M7-ANLL,[9] and, finally, with interstitial deletion of the long arms of chromosome 5.[10] Interestingly, two of the three cases reported by Bloomfield et al[1] had a 5q- interstitial deletion. It appears difficult to convincingly attribute the dysmegakaryocytopoietic status observed in those two patients to the 3q21 rearrangement alone. In conclusion, we believe that the criteria put forward by Bloomfield et al[1] in favor of this new cytogenetic-clinicopathologic association in ANLL are not specific enough. As suggested by the authors in their discussion, t(1;3)(p36;q21) should, at the present time, be considered as a variant form of rearrangement affecting band 3q21. Megakaryocytic proliferation and maturation appear to be under the control of complex genetic regulation. Molecular cloning of the 3q21 breakpoint may reveal valuable information on the molecular basis of megakaryocytic regulation.

To the Editor:

Gyger questions whether the t(1;3)(p36;q21) represents a specific clinicopathologic subset of acute nonlymphocytic leukemia (ANLL). Additional carefully studied cases will have to be reported before we can conclusively respond. However, our prior experience[1-4] suggests that once an entity is recognized and reported, others begin to find the entity, and thus delineation of its precise features becomes possible. Indeed, this already seems to be happening for the t(1;3). Since initial recognition of the entity by Moir et al,[5] there have already been at least 12 additional patients reported, and each month seems to bring new reports.[6-14] Unfortunately, the data reported on many of the patients are minimal. It is our hope that as a result of our detailed report,[8] others will comment on the recurring features we have found so we can see how characteristic they are.

Table 1 highlights a number of features found in the 14 patients for whom data are available. Nine had the t(1;3) as the sole cytogenetic abnormality; in four patients, additional abnormalities occurred, including a deletion 5q in three. The clinical picture seems to be similar regardless of whether there are additional chromosomal abnormalities. Most of the cases were difficult to classify according to French-American-British (FAB),[15,16] as is often the case in leukemias involving all cell lines (panmyeloses). A myelodysplastic syndrome was first diagnosed in six patients; in three of these, acute transformation was documented. A long preleukemic phase was documented in two additional patients. A history of prior chemotherapy or radiotherapy was found in only two patients; one had been treated for breast cancer and the other for polycythemia vera. There is a slight female preponderance, which is unusual in "carcinogenic" exposure-related leukemias. However, among the six males reported, one was a brick-factory worker, one a mason, and a third had spent the prior two years building his home. From an etiologic standpoint,

Table 1. Clinicopathologic Features at Time of Chromosome Study of 14 Patients With t(1;3)(p36;q21)

RAS, RA with ring sideroblasts; NA, not applicable; CT, chemotherapy; RT, radiotherapy; F, fail, no remission; CR, complete remission; ?, data not given; ↓, decreased; +, present; –, absent.

*To the extent possible, diagnosis is FAB.[15,16]

†Five months before chromosome study. Not given at time of chromosome study.

it is also of interest that we know of no cases reported from the United States.

Anemia (median hemoglobin, 7.5 g/dL) was present in all patients for whom data were provided. It was much more severe than reported in most large series of ANLL (University of Minnesota median, 9.5). The other striking hematologic feature at diagnosis was a high platelet count (median, 262 × 10^9/L); the median at the University of Minnesota is 62 × 10^9/L. Finally, response to chemotherapy has been poor. Seven patients have had intensive chemotherapy for ANLL; only one had a brief complete remission. Only two of the five failures had additional chromosomal abnormalities.

These data suggest to us that t(1;3)(p36;q21) does indeed identify a specific subtype of myeloid leukemia. It appears to be characterized by being a panmyelosis often difficult to classify according to FAB. Patients tend to present with low hemoglobins and high platelet counts, and response to standard ANLL therapy is poor. The importance of additional chromosomal abnormalities is unknown, but clearly the deletion 5q does not account for the above syndrome, since it occurred in only three of the patients. Which aspects of the syndrome, if any, are accounted for solely by the break in 3q21 is also unclear; Rowley's group has suggested that both a break at 3q21 and 3q26 are required for platelet abnormalities in situations other than t(1;3).[17]

How characteristic the megakaryocytic abnormalities we reported are is unknown, because others have not described the morphology in detail. Further cases must be studied to increase our understanding of this clinicopathologic entity, but for the present, the t(1;3)(p36;q21) seems to clearly identify an unusual subgroup of ANLL.

SERUM LACTIC DEHYDROGENASE ISOENZYME PATTERN IN CHILDHOOD LYMPHOBLASTIC LEUKEMIA

To the Editor:

We have read with great interest the recent article by Pui et al[1] describing the prognostic value of serum lactic dehydrogenase (LDH) levels in childhood acute lymphoblastic leukemia (ALL). Their results confirm our findings.[2]

In our study, in addition to elevation of serum LDH levels, isoenzyme patterns of LDH were also related to the prognosis of childhood ALL. The highest concentration of LDH-3 was observed in the high-risk group at the time of diagnosis. The ratio of LDH-3 to LDH-2 was found to be greater than 1.0 in more than 70% of children in the high-risk group but in none of the patients in the standard-risk group.

We believe that in addition to serum LDH values, the determination of its isoenzymes would be helpful in the identification of a high-risk group of children with ALL.

2. Hiçsönmez G, Çağlar K, Renda N: Prognostic value of the determination of serum lactic dehydrogenase and its isoenzymes in children with acute lymphoblastic leukemia. Scand J Haematol 34:256, 1985

To the Editor:

We are interested in the confirmatory finding of Hiçsönmez et al that children with acute lymphoblastic leukemia (ALL) and high serum lactic dehydrogenase (LDH) levels have poor prognosis features at diagnosis. We have recently studied the isoenzyme pattern of serum LDH in 29 children with ALL. Using the identical criteria to define risk groups,[1] in contrast to the findings of Hiçsönmez et al, we found no difference in the distribution of serum LDH isoenzymes between high- and standard-risk patients (see Table 1). None of the patients in the standard-risk group and only one in the high-risk group had a serum LDH-3-LDH-2 ratio over 1.0 at presentation ($P = 1.0$ by two-tailed Fisher exact test). The reason for this discrepancy is unclear but may be related in part to our use of fresh serum samples, as opposed to frozen samples in their study.[2] Although serum LDH level was found to have independent prognostic value, the pathophysiologic basis for an increase of serum LDH is poorly understood.[3]

Table 1. Distribution of Serum LDH Isoenzymes According to Risk Group

Feature	No. of Patients	Percentage (Mean ± SD) of Total Activity				
		LDH-1	LDH-2	LDH-3	LDH-4	LDH-5
High risk	21	12.4 ± 4	42.8 ± 6	28.9 ± 7	11.1 ± 3	5.2 ± 5
Standard risk	8	16.0 ± 3	47.6 ± 4	22.2 ± 4	9.6 ± 3	4.6 ± 1

ERRATUM

In the article entitled "Use of Oligonucleotide Hybridization in the Characterization of a β-Thalassemia Gene (β^{37}TGG → TGA) in a Saudi Arabian Family" by Boehm et al, which appeared in the April 1986 issue (Volume 67, Number 4, page 1185), Figure 2B was omitted. Figure 2 is reprinted in its entirety below.

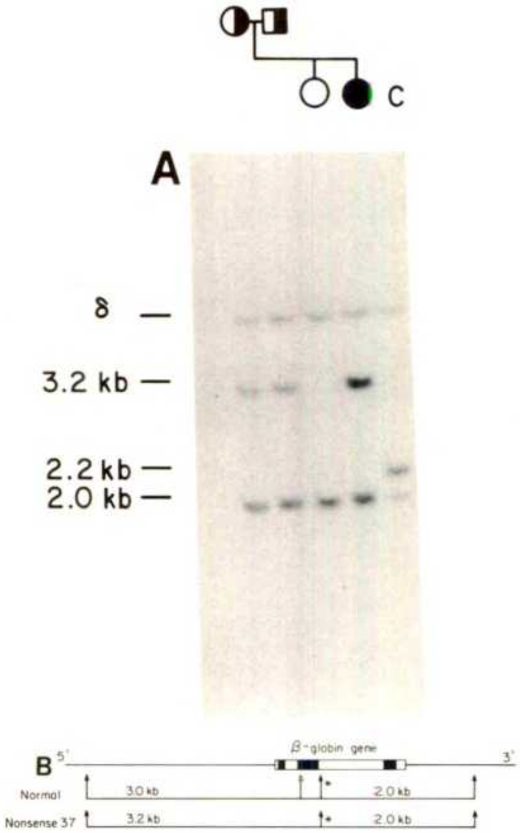

Fig 2. (A) Autoradiogram of *Ava*II-digested genomic DNA from family members indicated by the pedigree. β-Globin cDNA (JW 102) was used as the probe. The two alleles of an *Ava*II polymorphism in IVS 2 of the gene appear as 2.2-kb and 2.0-kb fragments on the autoradiogram. All family members are homozygous for the presence of the polymorphic site (+/+), and the control (c) is heterozygous +/−. A new band at 3.2 kb is seen in this family and is segregating with the β-thalassemia allele. The appearance of this fragment indicates loss of a nonpolymorphic *Ava*II site in exon 2 of the β-globin gene. Probe cross hybridizes with δ-globin sequences. (B) *Ava*-II restriction map of a normal β-globin gene and the mutant β-globin gene described in the text. Solid arrows (↑) indicate the locations of the nonpolymorphic *Ava*II restriction sites within and flanking the β-globin gene. Solid arrows with asterik (↑•) indicate the location of a polymorphic *Ava*II site, which is present in both the mutant and normal β-globin genes. Open arrow (⇡) indicates the location of the nonpolymorphic *Ava*II site, which is destroyed in the mutant gene. The 3.0-kb fragment is not seen in the autoradiogram in Fig 2a because the 5' end of the JW 102 β-globin cDNA probe is complementary to only about 50 bp of this fragment.

ANNOUNCEMENTS

RECENT ADVANCES IN LEUKEMIA AND LYMPHOMA

Organizers: Robert Peter Gale and David W. Golde

January 25–31, 1987;* Keystone, Colorado

Dramatic advances have been made during the last five years in the pathogenesis and basic biology of the leukemias and lymphomas. Research involving normal and neoplastic hematopoiesis and the molecular basis of hematopoietic cell transformation is at the very forefront of our understanding of human oncogenesis and the clinical treatment of human cancer. Key issues to be addressed at this meeting include abnormal gene expression and regulation of oncogenes and related genes, interrelationships between genetic abnormalities and hematopoietic growth factors, and the role of viruses in experimental and clinical leukemias and lymphomas. We also will consider current concepts of hematopoietic and lymphoid cell growth and development and the role of immunology in the diagnosis and therapy of these disorders. Therapeutic advances such as new drugs, treatment schedules, and bone marrow transplantation with and without *in vitro* treatment will be evaluated. New strategies such as gene transfer in hematopoietic cells will be discussed in the context of the biology of the leukemias, the introduction of drug resistance genes, and the correction of leukemia-specific genetic abnormalities. The integration of studies of basic biology, clinical features, and therapeutic advances will serve to summarize critically the current state of this rapidly evolving field and to develop future research strategies. Plenary session topics include: Chromosomes, DNA, and Leukemia; Oncogenes in Leukemia/Lymphoma; Viruses and Leukemia/Lymphoma; Growth Factors and Receptors; Hematopoietic Stem Cells and Differentiation; Immunology of Leukemia and Lymphoma; Gene Transfer into Hematopoietic Stem Cells; Therapy.

Related 1987 UCLA Symposia include: GROWTH REGULATION OF CANCER, January 17–23,* Park City, Utah; TUMOR PROGRESSION AND METASTASIS and ALTERED GLYCOSYLATION IN TUMOR CELLS (concurrent), April 6–12,† Keystone, Colorado; and THE T CELL RECEPTOR, April 12–17,† Keystone, Colorado.

Abstract Submission Deadlines: *, October 3, 1986; †, December 12, 1986. Applications will be accepted at any time for meetings which are not over-subscribed. *For further information,* please call or write: UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, CA 90024. Telephone: (213) 206-6292. Telex: UCLA Symposia 9103427597.

CONTEMPORARY TOPICS IN EXPERIMENTAL HEMATOLOGY

A Symposium in conjunction with the

15TH ANNUAL MEETING OF THE INTERNATIONAL SOCIETY OF EXPERIMENTAL HEMATOLOGY

August 10–14, 1986

Hyatt Regency Hotel, Buffalo, New York

PRESENTERS

Peter J. Quesenberry, MD, Charlottesville, Va.
Rainer Storb, MD, Seattle, Wash.
Bob Löwenberg, MD, Rotterdam, The Netherlands
Harvey D. Preisler, MD, Buffalo, NY
Shiman Slavin, MD, Jerusalem
Ronald Hoffman, MD, Indianapolis, Ind.
Jun Minowada, MD, Okayama, Japan
Malcolm S. Mitchell, MD, Los Angeles, Calif.
David W. Golde, MD, Los Angeles, Calif.
E. Richard Stanley, MD, Bronx, NY
John W. Adamson, MD, Seattle, Wash.
Hal E. Broxmeyer, MD, Indianapolis, Ind.
H. Philip Koeffler, MD, Los Angeles, Calif.

Selected Topics of the ISEH meeting: Stroma; Bone Marrow Transplantation; Growth Factors; Differentiation; Stem Cells; Myeloproliferative Disorders; Leukemia/Lymphoma.

Sponsored by the National Cancer Institute, the National Heart, Lung, and Blood Institute, and the National Institutes of Health. Fees: $160.00 for ISEH members; $185.00 for nonmembers. Registration for the ISEH meeting will be held August 9–10, 1986, at the Hyatt Regency Hotel. *For further information and preregistration,* contact M.P. McGarry, MD, Roswell Park Memorial Institute, 666 Elm Street, Buffalo, NY 14263. Preregistration ends July 15.

Blood, Vol 68, No 1 (July), 1986: pp 324–325

WILMOT CANCER RESEARCH FELLOWSHIPS

The University of Rochester School of Medicine offers research training to physicians who have completed at least one year of residency or research experience. Fellowships will begin July 1, 1987. Opportunities exist in any discipline relevant to the cause, diagnosis, treatment, or prevention of cancer, including endocrinology, experimental therapeutics, genetics, hematology, immunology, microbiology, molecular and cellular biology, pathology, and radiation oncology.

Beginning stipends range from $32,000 to $34,000, based on postgraduate experience. There is an annual allowance of $5,000 for related research costs. Support is provided for up to three years.

For further information, contact: Wilmot Cancer Research Fellowship Program, Medical Center Box 601, University of Rochester School of Medicine & Dentistry, 601 Elmwood Avenue, Rochester, New York USA 14642.

INTENSIVE REVIEW OF HEMATOLOGY-ONCOLOGY

Boston, Massachusetts

October 20–24, 1986

Sponsored by the Hematology Division, Brigham and Women's Hospital, and Harvard Medical School. *For further information, contact:* Harvard Medical School, Department of Continuing Education, Boston, MA 02115. Telephone: (617)732-1525.

The New York Academy of Sciences

BLOOD IN CONTACT WITH NATURAL AND ARTIFICIAL SURFACES

November 12-14, 1986

The Sheraton Centre, New York City

The purpose of this conference is to unite scientists from diverse disciplines, such as physical chemistry, the engineering sciences, biology and medicine to participate in a dialogue on the present status of surfaces and their relationship to thrombosis. This meeting will range from didactic presentations of basic concepts common to specific disciplines to state-of-the-art exchanges of ideas and methodologies among scientists studying the interaction of blood with prosthetic and naturally-derived surfaces.

There will be contributed poster sessions. The deadline for the submission of abstracts is July 31, 1986. A 200-word summary of the work to be presented should be sent to: Dr. Vincent Turitto, Mount Sinai Medical Center, Division of Cardiology/23rd Floor, 1 Gustave Levy Place, New York, NY 10029.

Chairs: Vincent Turitto, ScD., Mount Sinai Medical Center, NY; Edward Leonard, Ph.D., Columbia University, NY and; Leo Vroman, Ph.D., Brooklyn VA Hospital, NY.

Inquiries should be addressed to: Conference Department, The New York Academy of Sciences, 2 East 63rd Street, New York, NY 10021.

BLOOD BANK DIRECTOR

The American Red Cross Blood Services, Rochester Region, is seeking a blood bank director with an M.D. The applicant must have experience in blood banking and administration, have an interest in research and teaching, and be qualified for an academic appointment of the faculty of the University of Rochester School of Medicine and Dentistry.

The American Red Cross Blood Services, Rochester region provides all the blood products for 43 hospitals in a 15-county area. It collects 100,000 units of blood per year and produces 250,000 blood products. The director of Blood Services is responsible for a program staff of 170. The director interacts with leadership volunteers on a regular basis

Interested candidates should submit their curriculum vitae to: ***CHAIRPERSON, Search Committee, ℅ Personnel Department, American Red Cross, 50 Prince Street, Rochester, New York 14607.***

Equal Opportunity Employer/AA

ONCOLOGY

Veterans Administration Medical Center, Seattle and the University of Washington Division of Medical Oncology are recruiting for three positions. Director of the VA Marrow Transplant Unit, an established 6 bed referral center, closely affiliated with the Fred Hutchinson Cancer Center and currently performing 35 allogeneic transplants/year: Individual should have administrative skills, several years in transplantation, and an interest in clinical investigation. Two positions in general oncology: Individuals should have a laboratory based research program capable of generating independent funding. Equal Opportunity Employer. Hispanics, women, and other minorities encouraged to apply. Send CV to Charles E. Pope II, M.D., Acting Chief, Medical Service (111), VA Medical Center, 1660 S. Columbia Way, Seattle, WA 98108

RESEARCH SCIENTISTS EXPERIMENTAL HEMATOLOGY

Amgen, an established biotechnology company with a broad technological base is seeking **Research Scientists.** Qualified candidates will have a Ph.D. or M.D. degree and at least three years postdoctoral or equivalent experience involving *in vitro* and *in vivo* hematopoietic and immunological assays. Amgen currently has several major programs addressing the biological roles of **Human Lymphokines** and **Cytokines**. Our recent advances with **Interleukin-2, Erythropoietin** and a **Pluripotent Colony-Stimulating Factor** have made us a leader in the field of **Biological Response Modifiers.**

Amgen offers a stimulating research environment and maintains close association with academic institutions through research collaborations and its Scientific Advisory Board. Research activity at **Amgen** will lead to health care and industrial chemical products based on recombinant DNA and hygridoma technologies.

We offer an excellent salary and benefits package as well as equity participation. Applications including a curriculum vitae and the names of three references should be sent to:

BOARD REVIEW COURSE IN HEMATOLOGY
The George Washington University Medical Center Washington, DC
October 15–18, 1986

The Division of Oncology and Hematology of the George Washington University Medical Center is pleased to announce this course to be held at the Bethesda Hyatt Regency Hotel, October 15–18, 1986, conveniently located on the Metro, only minutes from downtown Washington.

Designed to meet the needs of physicians planning to take the hematology boards, the course will be a valuable update on the recent advances in hematology. It will satisfy requirements for up to 28 hours of category I, AMA credit. Course director is Lawrence Lessin, M.D.

Topics include:

- Red Blood Cell Disorders
- Coagulopathies and Anticoagulant Therapy
- Hematologic Malignancies
- Review of Blood and Marrow Morphology and Hematopathology
- Immunohematology
- Bone Marrow Transplantation
- Strategies for Examination

For further information contact: Greg P. Thomas, Office of Continuing Medical Education, The George Washington University Medical Center, 2300 K Street, N.W., Washington, DC 20037. (202) 676-4285.

EXPLORE THE IMMUNE SYSTEM IN A TOTALLY DIFFERENT WAY…CELLFREE™

Interleukin-2 receptors (IL-2R) are spontaneously released into the serum of patients with leukemias and other lymphoreticular malignancies.[1] Such patients can now be monitored using . . .

The First Serum Immunoassay for Soluble T Cell Markers

The CELLFREE™ Interleukin-2 Receptor Test Kit enables you to quantitate soluble or released interleukin-2 receptors in serum. This novel assay provides a new measure of immune system activation or dysfunction. Activated T cells in affected tissues and organs can now be evaluated, without invading the tissue, by assaying for serum soluble interleukin-2 receptors released by these localized T cells.

Changes in soluble interleukin-2 receptor levels have been observed in patients with lymphoreticular malignancies, immunodeficiency syndromes, and transplantation rejection.

CELLFREE™–The Convenient Measure of Immune System Activation

The CELLFREE™ procedure is a simple, rapid sandwich immunoassay using two non-competing monoclonal antibodies. Quantitative results are read colorimetrically from a 96-well microtiter plate.

No flow cytometer is needed.

CELLFREE™ – The Tool of Future Immune System Discoveries

There's a lot more to learn about the immune system. With products like the CELLFREE™ Interleukin-2 Receptor Test Kit, T Cell Sciences, Inc. is providing the tools needed for future immune system discoveries.

To see if the CELLFREE™ Interleukin-2 Receptor Test Kit can contribute to your research, simply complete and mail the coupon below. Or, for a headstart in your research, call our Technical Services Department at 617-864-0632.

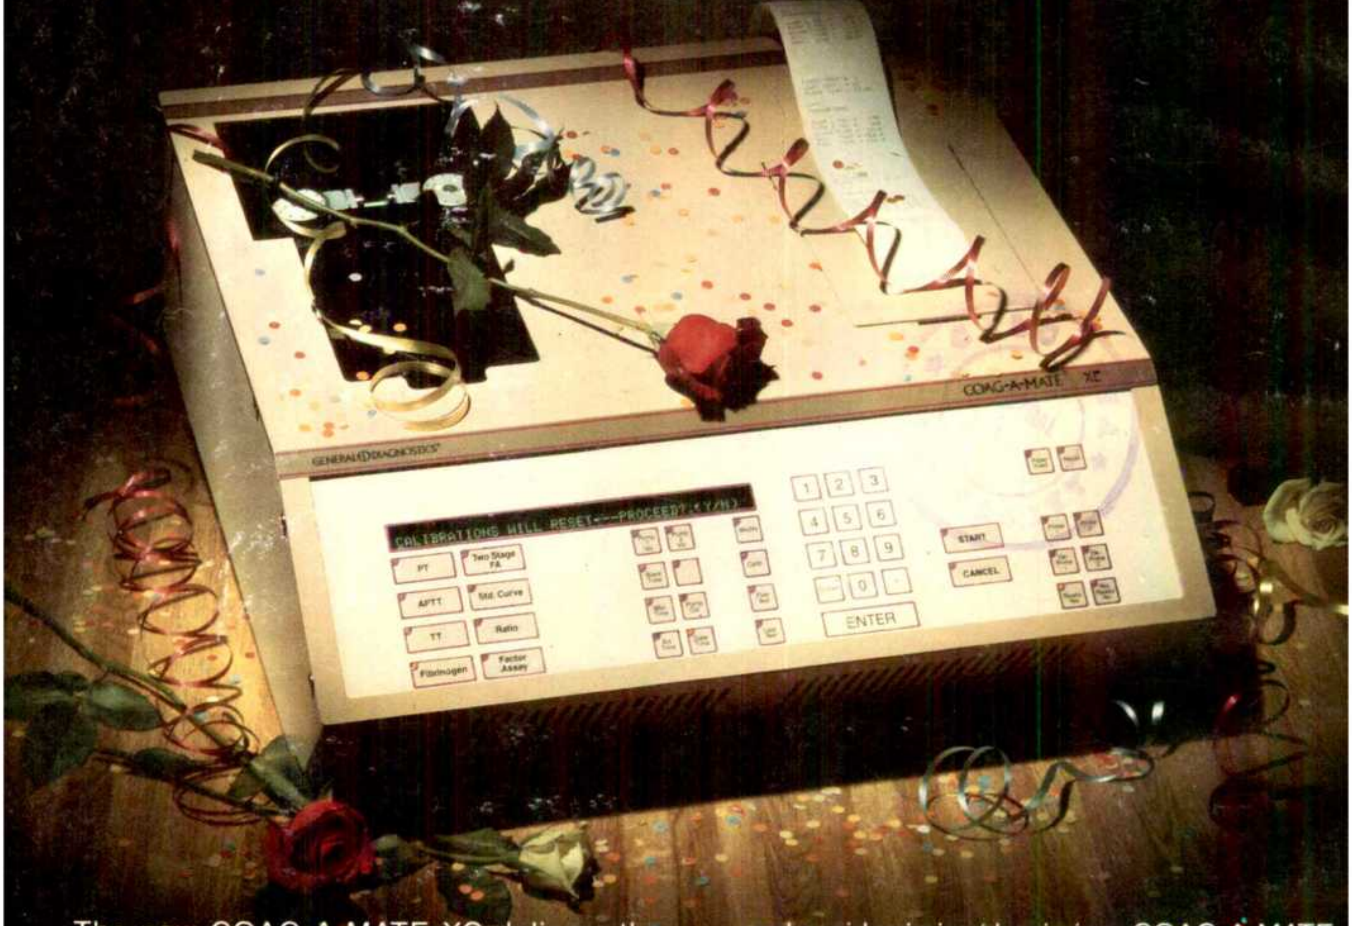
BRAVO!

Introducing the Versatile Performer
New COAG-A-MATE® XC



The new COAG-A-MATE XC delivers the versatile, reliable performance essential for today's coagulation testing needs.

- **Performance that's practical** — Does all key coagulation tests: PT, APTT, TT (thrombin time), fibrinogen and factor assays. Automated performance for rapid throughput.
- **Performance you can applaud** — Advanced programming allows all testing parameters to be temporarily or permanently modified by operator, with results expressed in %, ratio, seconds or mg/dl. Holds up to 15 standard curves in permanent memory.
- **Performance you can afford** — Equipped with numerous labor- and time-saving features, like semiautomated pump calibration and rapid priming/depriming, COAG-A-MATE XC is economical to operate and attractively priced for today's mid-sized laboratory.
- **Performance you can depend on** — Two separate self-checking diagnostic programs help ensure reliable performance and trouble-free operations.

NOW LESS COSTLY TO STOCK!
WELLCOVORIN TABLETS 5 mg IN NEW BOTTLES OF 20

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

atients Rescued

WELLCOVORIN® TABLETS
(leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.[1]

[1] Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

WELLCOVORIN® TABLETS
(leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

New! The latest edition of an authoritative reference book . . .

RED CELL METABOLISM

A MANUAL OF BIOCHEMICAL METHODS

Third Edition

ERNEST BEUTLER, M.D.

This third edition of **Red Cell Metabolism: A Manual of Biochemical Methods** presents a detailed discussion of the methods required for the measurement of red cell enzymes and metabolic intermediates. The techniques described—which have evolved after years of performing these assays in a laboratory environment—are essential both to the clinical diagnosis of certain types of anemia and to basic research on red blood cells. Topics covered include the fundamentals of handling blood samples, methods of reagent preparation, instrumentation, and calculation of results. New methods, improved procedures, and the increasing importance of certain red cell constituents such as GSH-S-transferase, superoxide dismutase, Na^+-K^+-ATPase, phosphoglycolate phosphatase, and creatine are among the factors that have brought about the need for this updated edition of the text.

Written for hematologists, clinical pathologists, biochemists, and cellular biologists, the third edition of **Red Cell Metabolism** represents the most authoritative and current information in the field of red cell enzymology, and is internationally recognized as the classic text on the subject.

CONTENTS:

Introduction: Purpose and Organization of the Manual. Red Cell Metabolism. **Basic Techniques and Equipment:** The Preparation of Red Cells for Assay. Reagents. Instrumentation. Calculation of Results. **Red Cell Glycolytic Enzymes:** Hexokinase (Hx). Glucose Phosphate Isomerase (GPI). Phosphofructokinase (PFK). Aldolase. Triose Phosphate Isomerase (TPI). Glyceraldehyde Phosphate Dehydrogenase (GAPD). Phosphoglycerate Kinase (PGK). Diphosphoglycerate Mutase (DPGM). Monophosphoglyceromutase (MPGM). Enolase. Pyruvate Kinase (PK). Lactate Dehydrogenase (LDH). **Red Cell Hexose Monophosphate Shunt and Other Enzymes:** Glucose-6-Phosphate Dehydrogenase (G-6-PD) and 6-Phosphogluconate Dehydrogenase (6-PGD). Glutathione Reductase (GR). Glutathione Peroxidase (GSH-Px). Glutathione S-Transferase. NADPH Diaphorase. NADH Methemoglobin Reductase (NADH-Ferricyanide Reductase). Superoxide Dismutase. Phosphoglucomutase (PGM). Glutamate-Oxaloacetate Transaminase (GOT). Phosphoglycolate Phosphatase. Adenylate Kinase (AK). Na^+-K^+ATPase and $\text{Mg}^{+\,+}$ATPase. Adenosine Demmainase (AD). Pyrimidine 5′ Nucleotidase. Acetylcholinesterase. Catalase. Galactose-1-Phosphate Uridyl Transferase. Galactokinase (GK). UDP Glucose-4-Epimerase (Epimerase). **Intermediate Compounds:** ATP. AMP and ADP. 2,3-Diphosphoglycerate (2,3-DPG). Reduced Glutathione (GSH). Oxidized Glutathione (GSSG). Creatine. Glucose. Pyruvate. Lactate. Glucose-6-P and Fructose-6-P. Glyceraldehyde-3-P (GAP), Dihydroxyacetone-P (DHAP), and Fructose-DiP (FDP). 3-Phosphoglyceric Acid (3-GPA). 2-Phosphoglyceric Acid (2-PGA) and Phosphoenolpyruvate. **Screening Techniques:** General Principles. Glucose Phosphate Isomerase Screening Test. Triose Phosphate Isomerase Screening Test. Pyruvate Kinase Screening Test. Glucose-6-Phosphate Dehydrogenase Screening Test. Glutathione Reductase Screening Test. NADH Methemoglobin Reductase (NADH Diaphorase). Pyrimidine 5′ Nucleotidase Screening Test. **Appendix 1:** Activities of Red Cell Enzymes in Normal Adults. **Appendix 2:** Effect of Temperature on Red Cell Enzyme Assays. **Appendix 3:** Levels of Intermediates in Red Cells of Normal Adults. **Appendix 4:** Frequently Used Molecular Weights.

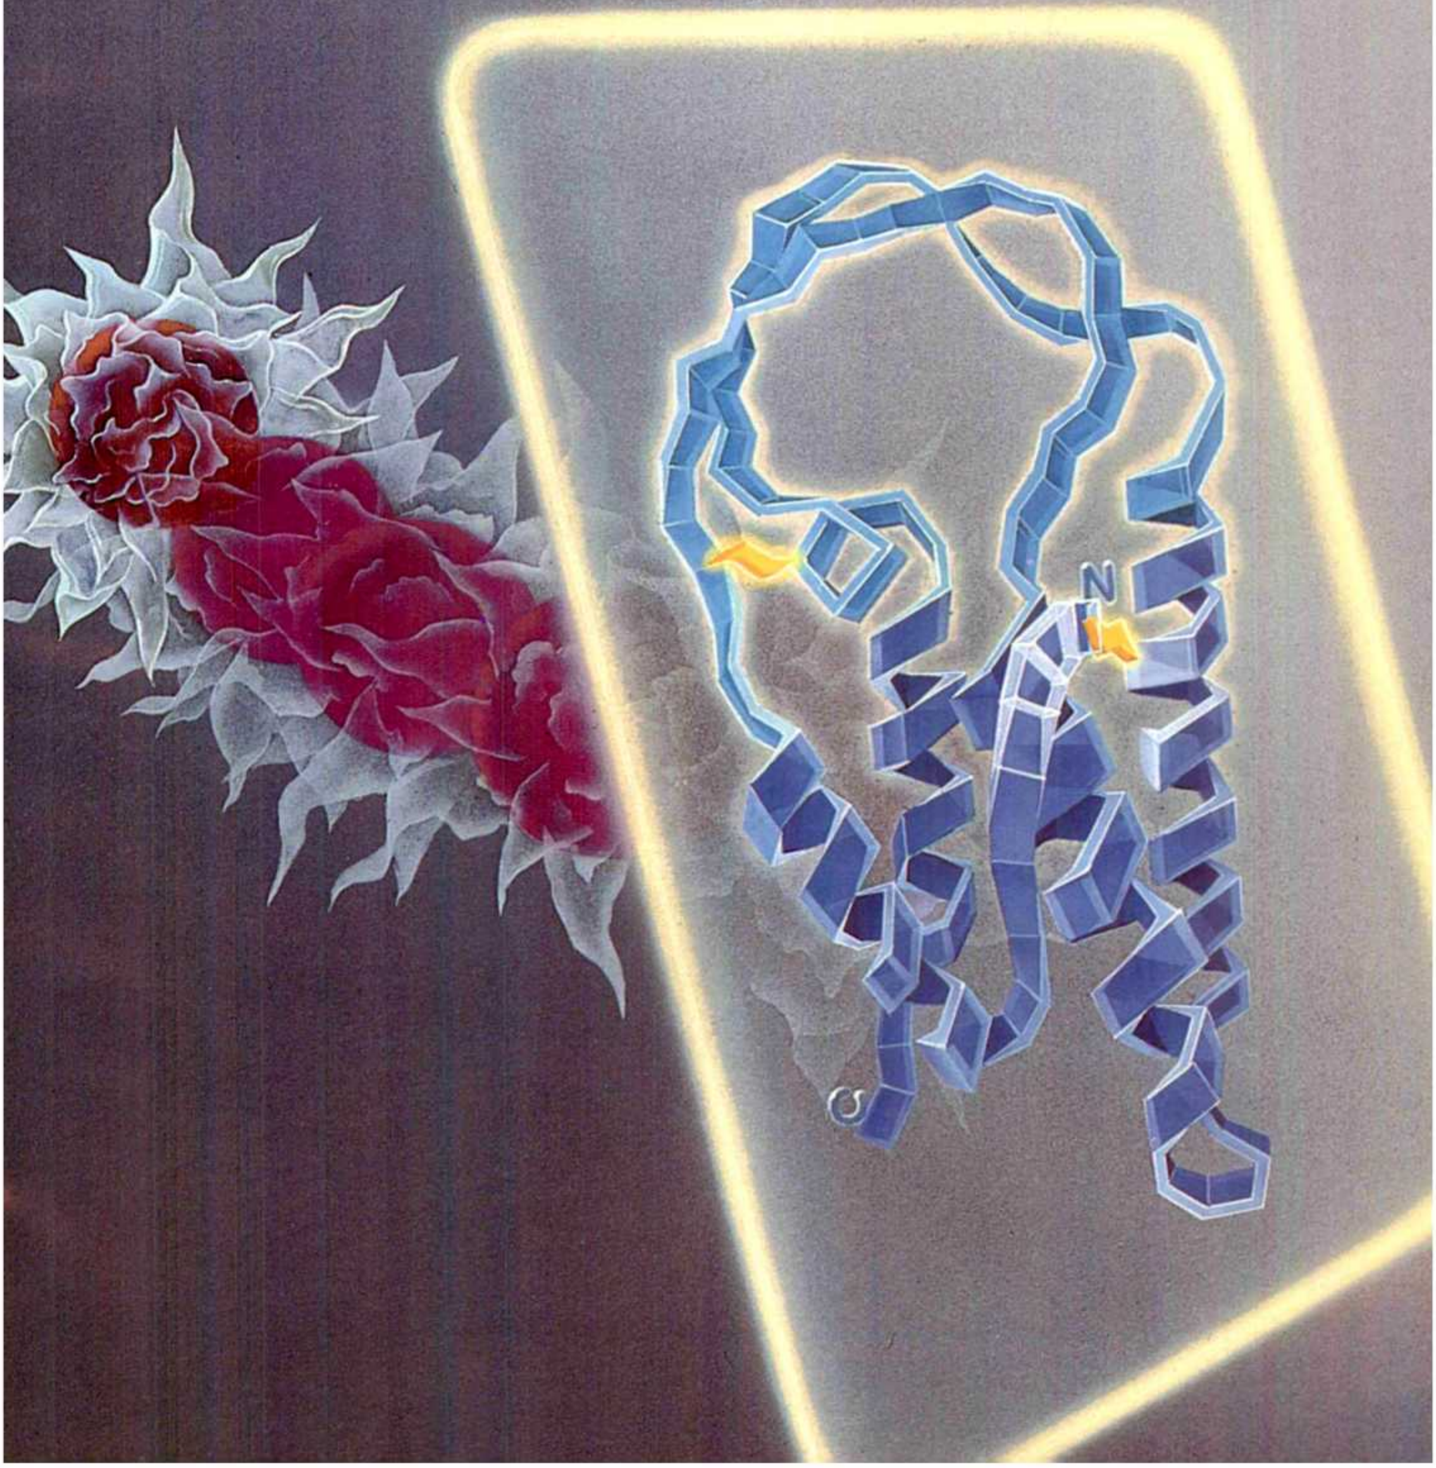
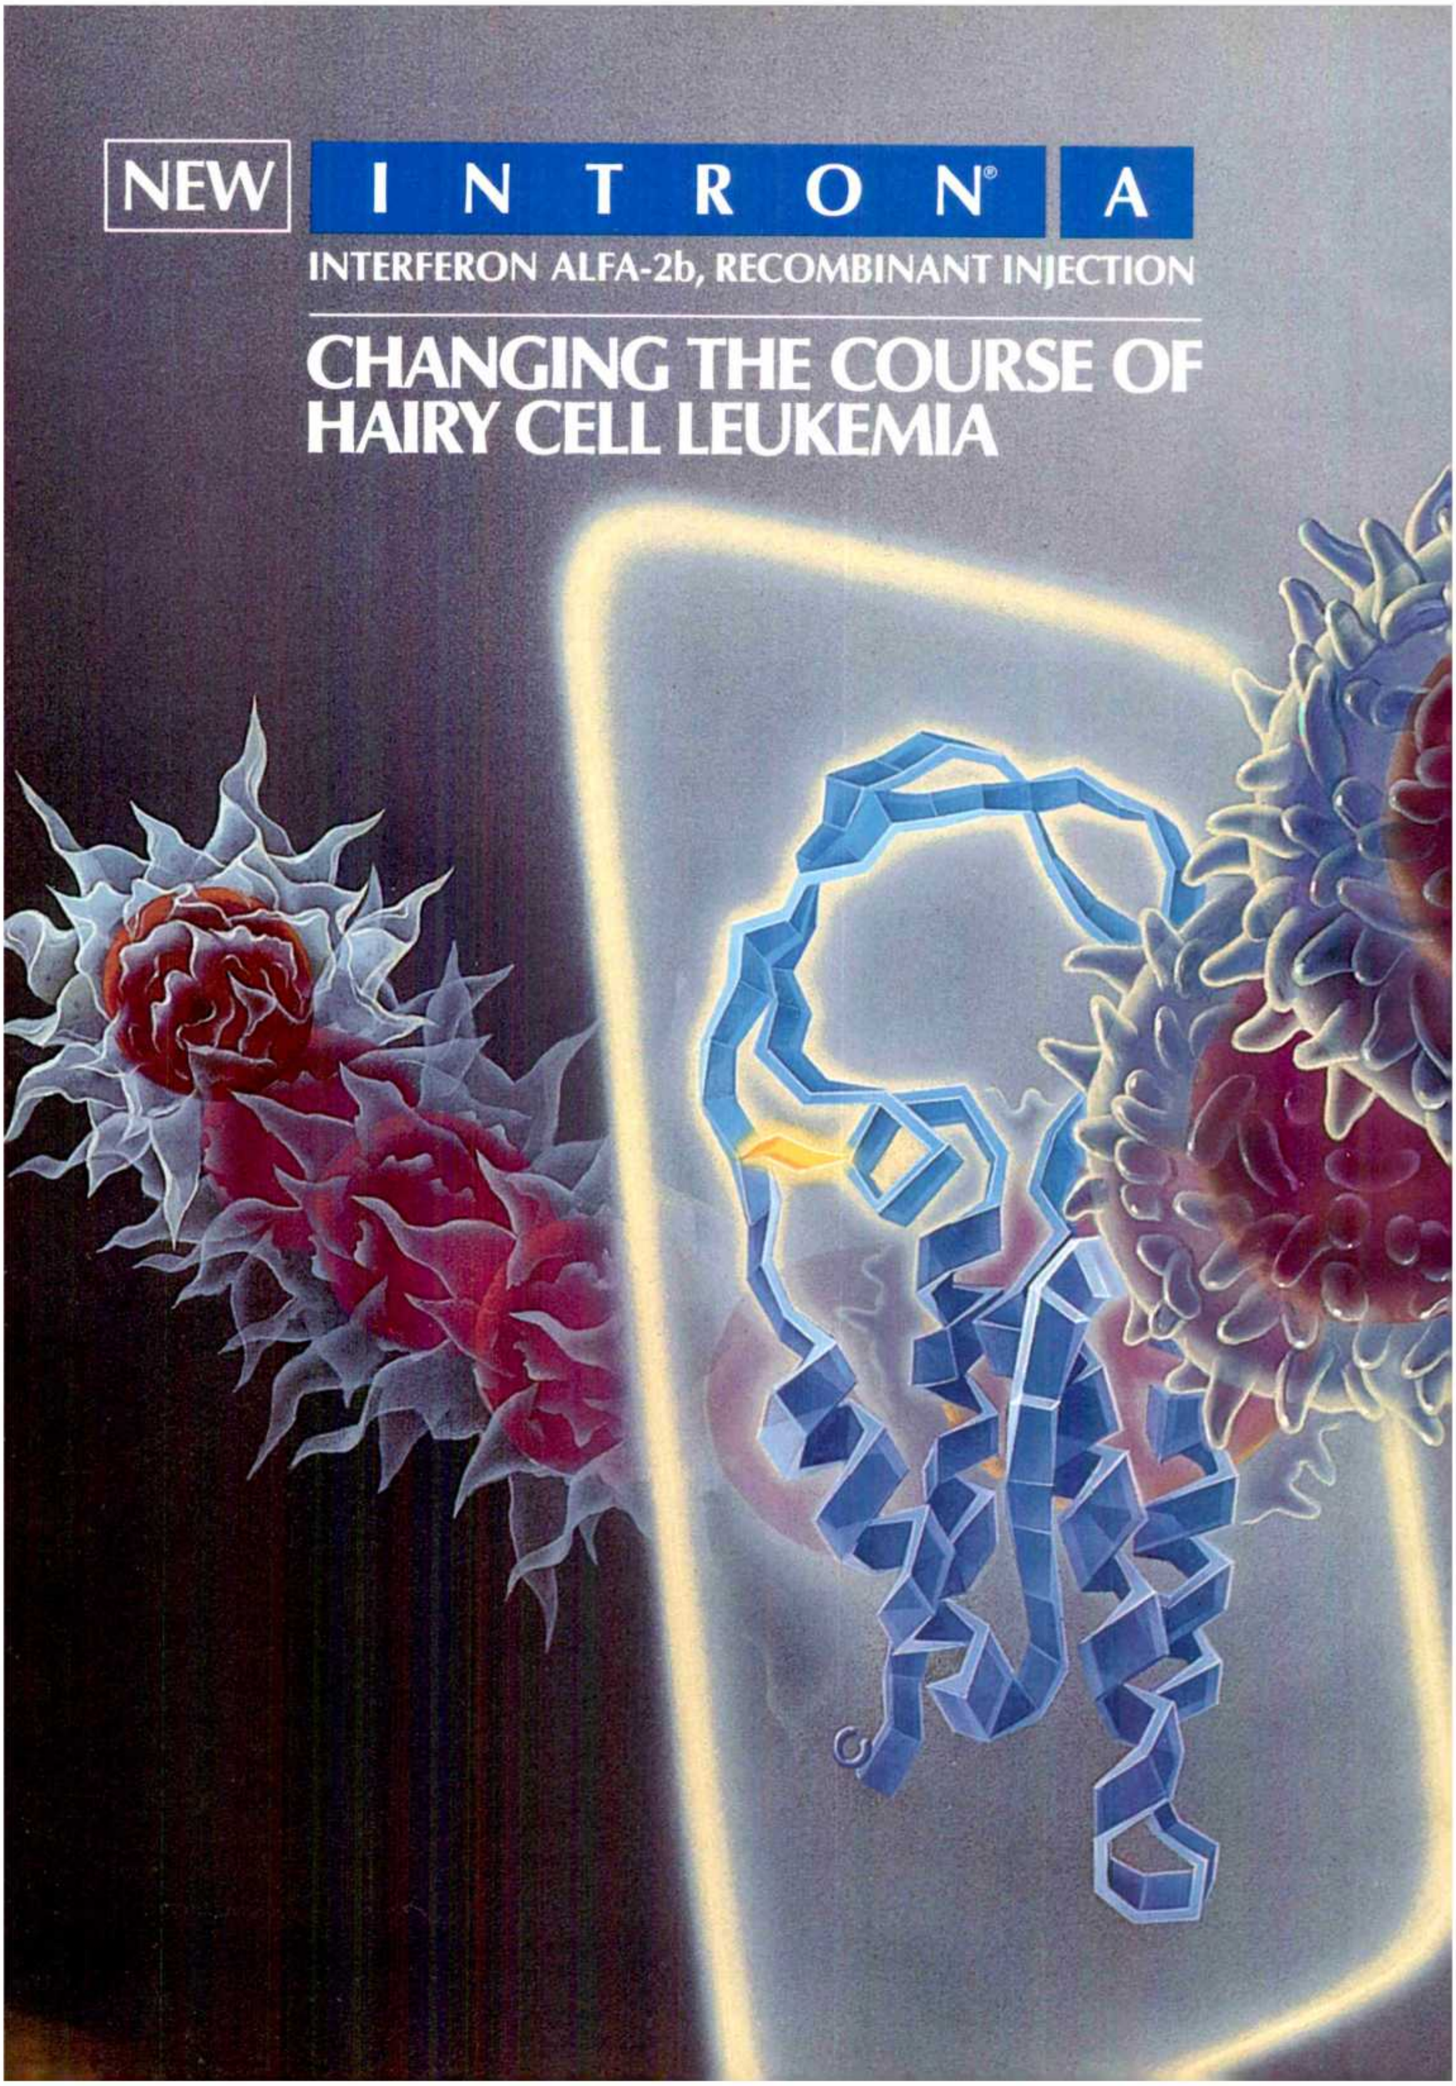
FROM ADVANCES IN BIOTECHNOLOGY...

NEW **INTRON® A**

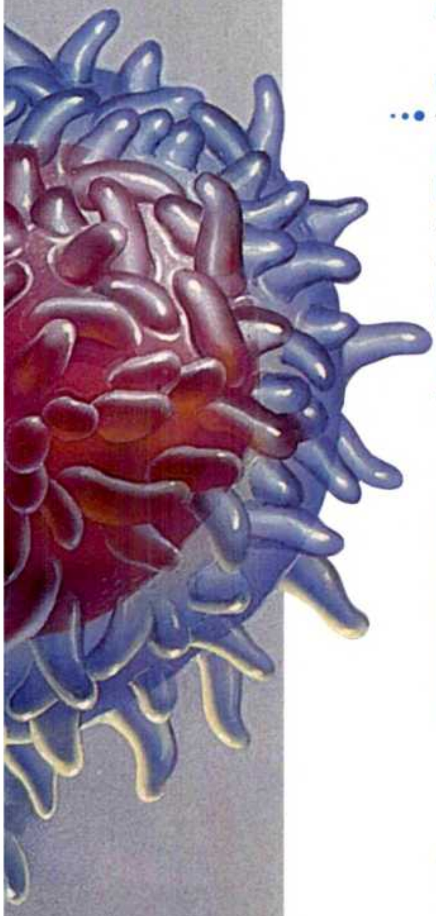
INTERFERON ALFA-2b, RECOMBINANT INJECTION

THE FIRST INTERFERON FROM SCHERING RESEARCH





NEW
INTRON® A
INTERFERON ALFA-2b, RECOMBINANT INJECTION
CHANGING THE COURSE OF HAIRY CELL LEUKEMIA



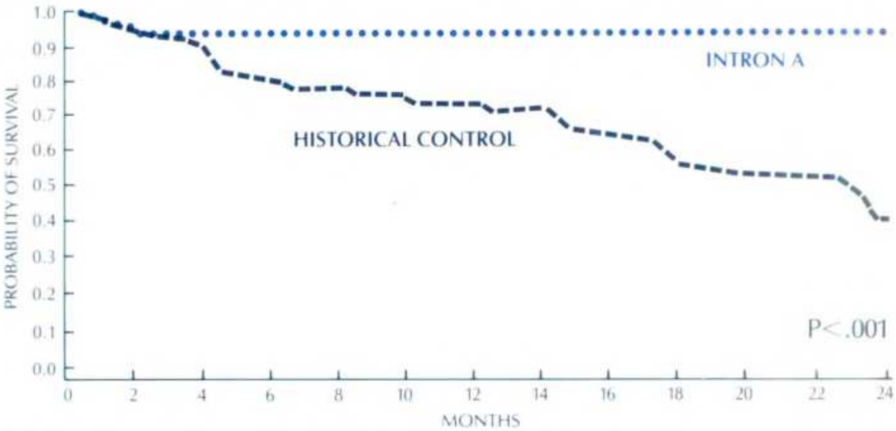
EFFICACY WELL ESTABLISHED

The efficacy of INTRON A was established in a 26-center clinical trial of 145 patients with progressive hairy cell leukemia, a B-cell malignancy.[1,2,3] INTRON A achieved a 74% objective response, measured as normalization of granulocyte, hemoglobin and platelet values and elimination of transfusion dependency.[1]

92% PROBABILITY OF SURVIVAL

In a separate analysis, a 24-month comparison was conducted between the INTRON A study population and historical controls.* After three months of therapy, patients receiving INTRON A reached and maintained a plateau of 92% probability of survival. The probability of survival among historical controls, however, declined steadily to 40% at 24 months.[1]

KAPLAN–MEIER ESTIMATED SURVIVAL CURVES



---

*Seventy-one historical control patients were treated with current standard therapies, 85% with chemotherapy (mainly chlorambucil) and 15% with supportive care.

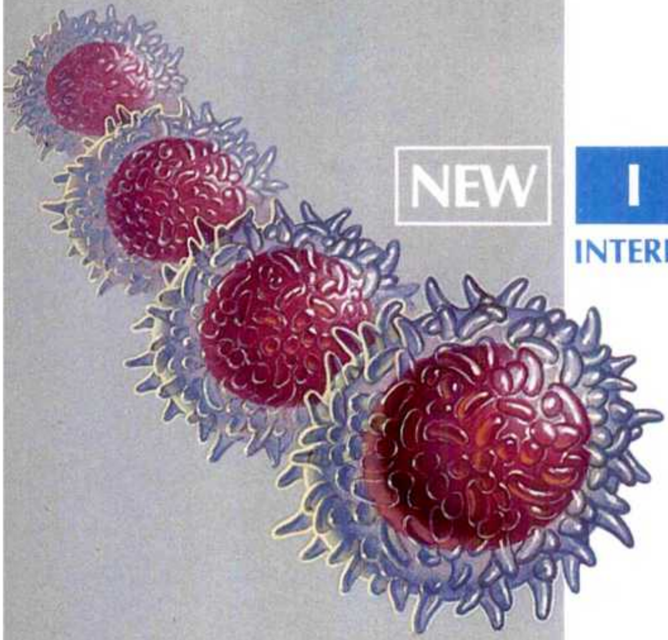
DRAMATIC CLINICAL IMPROVEMENTS

More than 80% of the study population achieved normal levels of platelets by three months, of hemoglobin by six months and of granulocytes by twelve months. Marked decreases in the incidence of life-threatening infections and transfusion dependency preceded normalization of hematologic values.[1]

THERAPY WELL TOLERATED

Treatment-related side effects were generally mild to moderate and rapidly reversible upon discontinuation of therapy. The predominant complaint was a flu-like syndrome, which usually diminished with continued therapy. Mild-to-moderate skin rashes occurred intermittently in 40% of the study population. A low incidence of mild-to-moderate GI disorders was also reported.[1]

For a brief summary of prescribing information, please see the following page.



NEW INTRON® A

INTERFERON ALFA-2b, RECOMBINANT INJECTION

A NEW CLASS OF CANCER THERAPY

A BIOLOGIC RESPONSE MODIFIER

To date, interferon actions in experimental systems have not been directly correlated with its clinical efficacy. However, as a biologic response modifier, interferon may modulate the immune system,[4,5,6] indirectly affect cell differentiation[7] and phenotypic expression[8,9] and enhance protection against viral infection.[10] In addition, interferon may have antiproliferative activity in experimental systems, seen as oncogene inhibition[11,12] and cytostatic action.[13,14,15]

99% PURITY

INTRON A production utilizes the new biotechnology of genetic engineering and Schering's advanced production process for assured purity.

PRODUCT INFORMATION

THE FIRST INTERFERON FROM SCHERING RESEARCH

INTRON® A Interferon alfa-2b recombinant for Injection

BRIEF SUMMARY

INDICATIONS AND USAGE INTRON A for Injection is indicated for the treatment of patients 18 years of age or older with hairy cell leukemia. Studies have shown that INTRON A can produce clinically meaningful regression or stabilization of this disease, both in previously splenectomized and non-splenectomized patients.

Prior to initiation of therapy, tests should be performed to quantitate peripheral blood hemoglobin, platelets, granulocytes and hairy cells and bone marrow hairy cells. These parameters should be monitored periodically during treatment to determine whether response to treatment has occurred. If a patient does not respond within 6 months, treatment should be discontinued. If a response to treatment does occur, treatment usually should be continued until no further improvement is observed and these laboratory parameters have been stable for about 3 months (see **DOSAGE AND ADMINISTRATION**). It is not known whether continued treatment after that time point is beneficial. Studies are in progress to evaluate this question.

CONTRAINDICATIONS INTRON A is contraindicated in patients with a history of hypersensitivity to interferon alfa or any component of the injection.

WARNINGS Moderate to severe adverse experiences may require modification of the patient's dosage regimen, or in some cases, termination of therapy with INTRON A.

Because of the fever and other "flu-like" symptoms associated with INTRON A administration, it should be used cautiously in patients with debilitating medical conditions, such as those with a history of cardiovascular disease (e.g., unstable angina, uncontrolled congestive heart failure), pulmonary disease (e.g., chronic obstructive pulmonary disease), or diabetes mellitus prone to ketoacidosis. Caution should also be observed in patients with coagulation disorders (e.g., thrombophlebitis, pulmonary embolism) or severe myelosuppression.

Patients with platelet counts of less than 50,000/mm^3 should not be administered INTRON A intramuscularly, but instead by subcutaneous administration.

Cardiovascular adverse experiences which include significant hypotension, arrhythmia, or tachycardia of 150 beats per minute or greater, were observed in approximately 3% of the patients studied who had various malignancies and were treated at doses higher than those for hairy cell leukemia. The incidence of these complications in patients with preexisting heart disease is unknown. Hypotension may occur during administration, or up to two days post therapy, and may require supportive therapy including fluid replacement to maintain intravascular volume. Supraventricular arrhythmias occurred rarely and appeared to be correlated with preexisting conditions, and prior therapy with cardiotoxic agents. These adverse experiences were controlled by modifying the dose or discontinuing treatment, but may require specific additional therapy.

Those patients with a recent history of myocardial infarction and/or previous or current arrhythmic disorder, who require INTRON A therapy, should be closely monitored (see **Laboratory Tests**).

Central nervous system effects manifested by depression, confusion and other alterations of mental status were observed in about 2% of hairy cell leukemia patients treated with INTRON A. The overall incidence in a larger patient population with other malignancies treated with higher doses of INTRON A was 10%. More significant obtundation and coma have been observed in some patients, usually elderly, treated at higher doses for other malignant diseases. These effects are usually rapidly reversible. In a few severe episodes, full resolution of symptoms has taken up to three weeks. Patients should be closely monitored until resolution of these effects. Discontinuation of INTRON A Interferon alfa-2b, recombinant for Injection therapy may be required. Narcotics, hypnotics, or sedatives may be used concurrently with caution.

Acute serious hypersensitivity reactions (e.g., urticaria, angioedema, bronchoconstriction, anaphylaxis, etc.) have not been observed in patients receiving INTRON A; however, if such an acute reaction develops, the drug should be discontinued immediately and appropriate medical therapy instituted. Transient cutaneous rashes have occurred in some patients following injection, but have not necessitated treatment interruption.

Laboratory abnormalities which occurred in hairy cell leukemia patients included elevated SGOT and SGPT, which occurred in 4% and 13% of patients, respectively. The overall incidences of laboratory abnormalities in a larger patient population with other malignancies, and treated at higher doses were somewhat higher. These included elevated liver function tests (SGOT, SGPT in 10% of patients) and reductions in granulocyte (20% of patients) and platelet counts (18% of patients) (see **Laboratory Tests**). These abnormalities are usually mild to moderate and transient. Severe abnormalities of these laboratory parameters are usually rapidly reversible upon cessation or reduction of INTRON A therapy.

PRECAUTIONS Information for Patients Patients being treated with INTRON A should be directed in its appropriate use, informed of benefits and risks associated with treatment and referred to the Patient Information Sheet.

Patients should be cautioned not to change brands of Interferon without medical consultation as a change in dosage may result.

It is advised that patients be well hydrated especially during the initial stages of treatment.

Laboratory Tests In addition to those tests normally required for monitoring patients with hairy cell leukemia, the following laboratory tests are recommended for all patients on INTRON A therapy, prior to beginning treatment and then periodically thereafter:

- Standard hematologic tests — including complete blood counts and differential as well as platelet counts.
- Blood chemistries — electrolytes and liver function tests.

Those patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer, should have electrocardiograms taken prior to and during the course of treatment.

Carcinogenesis, Mutagenesis, Impairment of Fertility Studies with INTRON A have not been performed to determine carcinogenicity, or the effect on fertility. Interferon may impair fertility. Mutagenicity studies with INTRON A revealed no adverse effects.

Studies in mice, rats, and monkeys injected with INTRON A for up to one month have revealed no evidence of toxicity. However, due to the known species-specificity of interferon, the effects in animals are unlikely to be predictive of those in man.

Pregnancy Category C Animal reproduction studies have not been conducted with INTRON A. It is also not known whether INTRON A can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. INTRON A should be given to a pregnant woman only if clearly needed. Another interferon alfa preparation has been shown to have abortifacient effects in *Macaca mulatta* (rhesus monkeys) when given at 20 to 500 times the human dose. Therefore, INTRON A should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. In studies of interferon use in non-human primates, abnormalities of the menstrual cycle have been observed.

INTRON A Interferon alfa-2b, recombinant for Injection should be used with caution in fertile men and women.

Nursing Mothers It is not known whether this drug is excreted in human milk. However, studies in mice have shown that mouse interferons are excreted into the milk. Because of the potential for serious adverse reactions from INTRON A in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use Safety and effectiveness have not been established in patients below the age of 18 years.

ADVERSE REACTIONS Adverse reactions to INTRON A are dose-related. In studies of patients with malignancies other than hairy cell leukemia, hematologic and hepatic toxicities were more common in patients receiving individual injections greater than 10 million IU, than in patients receiving less than this amount. Hematologic, hepatic, cardiovascular and neurologic toxicities were more common in patients receiving more than 30 million IU per injection than in patients receiving less than that amount.

The following adverse reactions were reported to be possibly or probably related to INTRON A therapy during clinical trials. The most frequently reported adverse reactions were flu-like symptoms, primarily fever, fatigue, and chills which occurred in almost all patients treated. Other organ systems in which reactions occurred in more than 5% of the patients are:

General — Taste alteration, anorexia and weight decrease occurred uncommonly.

Cardiovascular — Mild hypotension was frequently recorded although it was rarely symptomatic. Hypertension also occurred less commonly. Tachycardias occurred uncommonly usually in association with high fevers.

Gastrointestinal System — Nausea was common, although vomiting occurred rarely. Mild diarrhea was reported less commonly.

Hematologic — Mild thrombocytopenia and transient granulocytopenia occurred commonly.

Musculo-Skeletal System — Myalgia and arthralgia occurred commonly, usually in association with other flu-like symptoms.

Nervous System — Headache, somnolence, confusion, and dizziness occurred uncommonly. Ataxia and paresthesia were rare.

Psychiatric — Anxiety, depression and nervousness occurred uncommonly.

Skin and Appendages — Mild pruritus occurred uncommonly. Mild alopecia was uncommon. Various transient, mild skin rashes were seen frequently in patients with hairy cell leukemia.

Other Adverse Reactions — The following adverse reactions were reported with an incidence of 5% or less: leg cramps, constipation, insomnia, herpetic eruptions, non-herpetic cold sores, urticaria, hot flashes, supraventricular arrhythmias, epistaxis, stomatitis, paralytic ileus, dehydration, coagulation disorder (elevated PT and PTT), abnormal vision, tremor, emotional lability, chest pain, pharyngitis and syncope.

Adverse reactions reported rarely (less than 1%) were dyspepsia, purpura, dyspnea, sneezing, oculomotor paralysis, nasal congestion, flatulence, increased saliva, hyperglycemia, and ulcerative stomatitis.

Laboratory Value Changes — Those patient laboratory values which were normal to moderately abnormal (WHO grades 0–2) at baseline that worsened to either severe or life-threatening abnormalities (WHO grades 3 or 4) during some phase of treatment included: WBC, platelets, granulocytes, SGOT, creatinine, SGPT, LDH, and alkaline phosphatase.

DOSAGE AND ADMINISTRATION The recommended dosage of INTRON A for Injection for the treatment of hairy cell leukemia is 2 million IU/m^2 administered intramuscularly (see **WARNINGS**) or subcutaneously 3 times a week. Higher doses are not recommended. The normalization of one or more hematologic variables usually begins within 2 months of initiation of therapy. Improvement in all three hematologic variables may require 6 months or more of therapy.

This dosage regimen should be maintained unless the disease progresses rapidly, or severe intolerance is manifested. If severe adverse reactions develop, the dosage should be modified (50% reduction) or therapy should be temporarily discontinued until the adverse reactions abate. If persistent or recurrent intolerance develops following adequate dosage adjustment, or disease progresses, treatment with INTRON A Interferon alfa-2b, recombinant for Injection should be discontinued. The minimum effective dose of INTRON A has not been established.

At the discretion of the physician, the patient may self-administer the dose. The medication may be administered at bedtime.

HOW SUPPLIED INTRON A Interferon alfa-2b, recombinant for Injection is available in 3-, 5-, 10- and 25-million IU vials, each packaged with its own diluent.

Store INTRON A for Injection, both before and after reconstitution, between 2° and 8°C (36° and 46°F).

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to: John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1986, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $30.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus.* (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

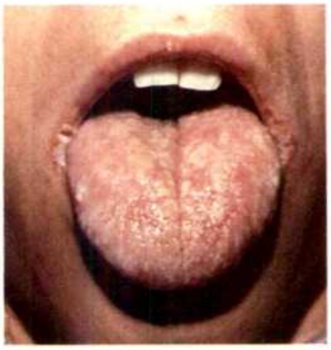
REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

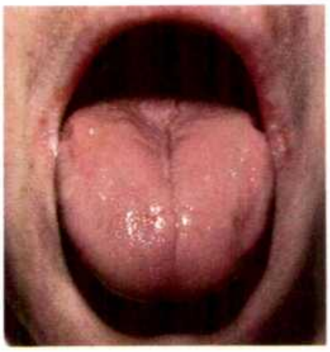
ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

The first troche treatment for oropharyngeal candidiasis.



Before treatment.[1]



After treatment with MYCELEX Troche.[1]

High clinical cure* rates.

A clinical cure rate of 96% was achieved in one randomized double-blind trial[2] in which MYCELEX Troche was administered to patients with oropharyngeal candidiasis. Other investigators have concluded that MYCELEX Troche "is highly effective treatment for chronic oral candidiasis."[3]

Dramatic improvement in symptoms.

Patients attain a high degree of relief at the end of therapy, as evidenced by the dramatic decrease in severity of glossitis, patches, perleche, pain, and other clinical signs and symptoms of thrush.[4]

Good patient acceptance, minimal side effects.

With MYCELEX Troche, messy suspensions and lengthy swishing are things of the past. MYCELEX Troche has a pleasant, slightly sweet taste. And an entire day's therapy—5 troches—can easily be carried in pocket or purse.

Based on a study of 52 episodes of oropharyngeal candidiasis, the investigators stated: "We believe that the troche form of clotrimazole...in the treatment of thrush in any patient population...is both effective and safe."[2†]

*Clinical cure is defined as absence of signs and symptoms of the disease.

†See adjacent page for summary of prescribing information, including contraindications and adverse reactions.

Mycelex® Troche

(clotrimazole) 10 mg

The only troche
for oropharyngeal
candidiasis.

MYCELEX® (clotrimazole) TROCHE

Indications and Usage: Mycelex Troches are indicated for the local treatment of oropharyngeal candidiasis. The diagnosis should be confirmed by a KOH smear and/or culture prior to treatment.

Contraindications: Mycelex Troches are contraindicated in patients who are hypersensitive to any of the components.

Warning: Mycelex Troches are not indicated for the treatment of systemic mycoses.

Precautions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials. In most cases the elevations were minimal and it was often impossible to distinguish effects of clotrimazole from those of other therapy and the underlying disease (malignancy in most cases). Periodic assessment of hepatic function is advisable particularly in patients with preexisting hepatic impairment.

Since patients must be instructed to allow each troche to dissolve slowly in the mouth in order to achieve maximum effect of the medication, they must be of such an age and physical and/or mental condition to comprehend such instructions.

Carcinogenesis: An 18-month dosing study with clotrimazole in rats has not revealed any carcinogenic effect.

Usage in Pregnancy: Pregnancy Category C. Clotrimazole has been shown to be embryotoxic in rats and mice when given in doses 100 times the adult human dose (in mg/kg), possibly secondary to maternal toxicity. The drug was not teratogenic in mice, rabbits, and rats when given in doses up to 200, 180, and 100 times the human dose.

Clotrimazole given orally to mice from nine weeks before mating through weaning at a dose 120 times the human dose was associated with impairment of mating, decreased number of viable young, and decreased survival to weaning. No effects were observed at 60 times the human dose. When the drug was given to rats during a similar time period at 50 times the human dose, there was a slight decrease in the number of pups per litter and decreased pup viability.

There are no adequate and well-controlled studies in pregnant women. Clotrimazole troches should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Pediatric Use: Safety and effectiveness of clotrimazole in children below the age of three years have not been established; therefore, its use in such patients is not recommended.

Adverse Reactions: Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials (see Precautions section).

Nausea and vomiting was reported in about one in 20 patients.

Dosage and Administration: Mycelex Troches are administered only as a lozenge that must be dissolved slowly in the mouth. The recommended dose is one troche five times a day for 14 consecutive days. Only limited data are available on the safety and effectiveness of the clotrimazole troche after prolonged administration; therefore, therapy should be limited to short-term use, if possible.

How Supplied: Mycelex Troches—white, discoid, uncoated tablets are supplied in bottles of 70 and 140. Each tablet will be identified with the following: Miles 095.

Store below 86°F (30°C), avoid freezing.

NEW

THE ONLY LIQUID IGIV

At least 98% IgG

Ready to use without reconstitution

*Confirmed in vitro inactivation of HTLV-III virus**

NEW NATIVE IGIV

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

LIQUID NATIVE IGIV...PURE AND SIMPLE

**The Cohn-Oncley process used to produce GAMIMUNE® N has been challenged in vitro with a virus spike of 1×10^5 of HTLV-III and found to remove and/or inactivate the viral challenge.[1] In addition, GAMIMUNE® N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 reduction of HTLV-III.[1] In a separate study conducted by the Food and Drug Administration,[2] an in vitro challenge at each of six fraction steps using HTLV-III demonstrated a cumulative reduction of greater than 1×10^{15} infectious units.*

Please see following page for brief summary of prescribing information

NEW NATIVE IGIV

GAMIMUNE® N
Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune® N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune® N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 40% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune® N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune® N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune® N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune® N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune® N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune® N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune® N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune® N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune® N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune® N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune® N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune® N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune® N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune® N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune® N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1-5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune® N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune® N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune® N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune® N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune® N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune® N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune® N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune® N. It is not known whether Gamimune® N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune® N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune® N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune® N. Symptoms reported with Gamimune® N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune® N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune® N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune® N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune® N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune® N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune® N for prophylaxis in immunodeficiency syndromes is 100-200 mg/kg (2-4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune® N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune® N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune® N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune® N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

*Blenoxane**

(sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{co}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{co} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{co} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain $FI\ O_2$ at concentrations approximately that of room air (25%) during surgery and the post-operative period.
(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate NDC 0015-3010-20

An important new book designed to aid the professional!

POORLY DIFFERENTIATED NEOPLASMS AND TUMORS OF UNKNOWN ORIGIN

Edited by

MEHMET F. FER, M.D., ROBERT K. OLDHAM, M.D., and
F. ANTHONY GRECO, M.D.

Clinical Oncology Monographs Series
Series Editors: **John W. Yarbro, M.D., Ph.D., Richard S. Bornstein, M.D., and Michael J. Mastrangelo, M.D.**

This important new book reviews in detail the diagnostic techniques, clinical syndromes, and therapeutic approaches to poorly differentiated neoplasms and tumors of unknown origin.

The interdisciplinary coverage in the text includes comprehensive discussions of the role of the pathologist in the evaluation of these malignancies, followed by general diagnostic techniques, tumor markers, commonly seen clinical syndromes, and new experimental methods.

Poorly Differentiated Neoplasms and Tumors of Unknown Origin will aid the oncologist, pathologist, internist, and hematologist with the difficult classification and selection of therapy for patients with these disorders.

CONTENTS: Contributors. *Mehmet F. Fer, F. Anthony Greco, and Robert K. Oldham.* Introduction. *Bruce Mackay and Nelson G. Number one in a series of typical case presentations.

Esophagitis in a leukemia patient

In patients with hematologic malignancies, the visceral organ most frequently involved by herpes simplex virus (HSV) infection is the esophagus.[1] Extensive ulcerative lesions may develop on the upper two thirds of the esophagus with confluent lesions of the distal third.[2] In some cases, however, the mucosa may be grossly unremarkable even when microscopic examination shows evidence of herpetic ulcerative esophagitis.[1] Similarly, some patients may display symptoms of dysphagia and burning retrosternal pain,[3] whereas others may appear asymptomatic.[1] The diagnostic method of choice for patients with suspected herpetic esophagitis is esophagoscopy with visualization of the mucosa and procurement of cytologic and biopsy specimens from ulcerated areas.[1]

Herpetic infections may result in extensive disease and death

Immunocompromised patients are highly vulnerable to HSV infection. Such infections may interrupt therapy and even lead to death if not detected early and managed aggressively.[1] Although the initial appearance may be mild, HSV infection may progress to severe localized mucocutaneous ulcerations. The greatest threat that herpes simplex poses is an infection that disseminates from a mucocutaneous or unrecognized primary lesion and involves the lungs, liver, esophagus, or central nervous system.[1] Furthermore, herpetic ulcers frequently provide an entry for secondary bacterial and fungal pathogens.[2]

Infections may not be diagnosed correctly without virologic study

Some investigators claim that the actual incidence of serious HSV infection is probably higher than reported because "the possibility of herpetic disease is insufficiently considered and appropriate diagnostic viral studies are often not carried out."[3] One study, for example, found histocytologic evidence of visceral herpes infection in 56 patients even though herpetic involvement was not suspected in any of the patients prior to autopsy.[2]

ZOVIRAX I.V. halts viral replication and speeds healing even in debilitated patients

ZOVIRAX I.V. has been shown to be a highly effective treatment for severe mucocutaneous HSV infection in immunocompromised patients. In controlled trials, ZOVIRAX I.V. rapidly halted viral shedding — within 3 days in most patients — and significantly shortened healing time as well as duration of pain.[4,5] Furthermore, ZOVIRAX I.V. may allow patients to return home sooner and enable patients with intraoral lesions to resume normal eating habits.[6]

ZOVIRAX I.V. is well tolerated by immunocompromised patients

A multicenter collaborative trial of ZOVIRAX I.V. in immunocompromised patients reported that: "Clinical benefits were obtained without appreciable toxicity. The most common reactions were irritation of peripheral veins used for drug infusion and a low incidence of rash.... Significant renal or hematologic toxicity did not occur, even in these seriously ill patients who were commonly receiving other drugs concomitantly."[5]

Note: Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes. Please see brief summary for more information.

An effective response to a life-threatening infection
ZOVIRAX® I.V. INFUSION
(acyclovir sodium) sterile powder

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION
(acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously, or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.
